| Hypogonadal | 4.25 (5.79) | 8.87 (6.04) | 9.00 (5.07) |

Standard error of means are given in parentheses.

eugonadal-treated and eugonadal-placebo groups reported significantly lower levels of irritability overall than the hypogonadal group (Table 4).

3.6.4. State self-esteem

A significant main effect was found for both time [$F(2,68) = 4.86$, $P < .05$] and group [$F(2,34) = 3.28$, $P < .05$], with the Time \times Group interaction approaching significance [$F(4,68) = 2.39$, $P = .059$]. The significant main effect for time is accounted for by the increase in self-esteem scores from 49.86 at Week 4 to 51.70 at Week 8 ($t = 2.13$, $P < .05$), in particular by the increase reported by the hypogonadal group from Weeks 4 to 8 (53.25 vs. 58.37). This finding (Table 4) reflects the trend towards a significant interaction, suggesting the existence of a positive treatment effect on self-esteem in the hypogonadal group.

3.6.5. Assertiveness

A significant main effect was found for time [$F(2,68) = 6.44$, $P < .01$] but not for group [$F(4,68) = 1.24$, ns] or their interaction [$F(2,34) = 1.09$, ns]. Table 4 shows substantial increases in assertiveness at Week 4 compared with Week 0, particularly in the eugonadal-treated and hypogonadal groups.

3.7. Profiles of Mood States

3.7.1. Total mood disturbance

Significant main effects were found for time [$F(4,136) = 6.72$, $P < .01$], for group [$F(2,34) = 13.04$, $P < .01$], and for

Fig. 2. Total mood disturbance in all groups at baseline (week 0), week 4 and week 8.

the Time \times Group interaction [$F(8,136) = 3.320$, $P < .01$]. Multiple comparisons found that the significant group effect was accounted for by significantly higher levels of total mood disturbance in the hypogonadal group than the eugonadal-treated and eugonadal-placebo groups (see Fig. 2). However, there was a significant reduction in total mood

scores in the hypogonadal group by Weeks 1–2 explaining the significant interaction effect ($t = 3.07$, $P < .05$).

3.7.2. POMS subscales

POMS subscale scores are shown in Table 5. Significant main effects were found for time for tension–anxiety

Table 5
Descriptive statistics for subscales on POMS at Weeks 0, 1–2, 3–4, 5–6, and 7–8

| Group | Week 0 | Week 1–2 | Week 3–4 | Week 5–6 | Week 7–8 |
|-------------------------------|--------------|--------------|--------------|--------------|--------------|
| <i>Tension–anxiety</i> | | | | | |
| Eugonadal-treated | 6.64 (1.09) | 7.71 (1.45) | 5.71 (0.99) | 5.21 (1.10) | 6.68 (1.35) |
| Eugonadal-placebo | 6.40 (1.16) | 5.80 (0.98) | 4.90 (0.76) | 5.30 (0.89) | 4.77 (0.79) |
| Hypogonadal | 17.37 (1.84) | 9.75 (1.12) | 11.63 (1.72) | 11.38 (1.89) | 12.00 (2.01) |
| <i>Depression–dejection</i> | | | | | |
| Eugonadal-treated | 5.07 (1.29) | 5.93 (1.45) | 2.93 (1.20) | 1.68 (0.50) | 1.82 (0.65) |
| Eugonadal-placebo | 5.73 (2.05) | 4.37 (1.34) | 2.70 (0.85) | 3.60 (1.67) | 2.23 (1.20) |
| Hypogonadal | 20.13 (3.83) | 11.25 (3.55) | 12.06 (4.03) | 12.69 (4.08) | 11.44 (3.32) |
| <i>Anger–hostility</i> | | | | | |
| Eugonadal-treated | 7.29 (1.88) | 9.11 (2.20) | 4.86 (1.28) | 3.46 (0.83) | 5.54 (1.79) |
| Eugonadal-placebo | 3.73 (1.33) | 4.03 (0.82) | 4.10 (0.82) | 4.00 (0.99) | 3.13 (0.67) |
| Hypogonadal | 17.75 (2.37) | 12.06 (2.90) | 17.69 (2.70) | 16.88 (2.85) | 14.75 (1.95) |
| <i>Vigor–activity</i> | | | | | |
| Eugonadal-treated | 20.79 (1.63) | 18.36 (1.70) | 18.43 (1.71) | 17.89 (1.87) | 17.79 (2.00) |
| Eugonadal-placebo | 17.06 (1.41) | 16.50 (1.46) | 17.87 (1.24) | 16.47 (0.98) | 16.87 (1.04) |
| Hypogonadal | 10.63 (2.26) | 15.88 (2.22) | 17.06 (1.80) | 14.75 (1.71) | 17.50 (1.75) |
| <i>Fatigue–inertia</i> | | | | | |
| Eugonadal-treated | 7.36 (1.44) | 7.43 (1.25) | 4.25 (0.71) | 4.32 (0.76) | 6.50 (1.52) |
| Eugonadal-placebo | 6.47 (1.01) | 8.40 (1.05) | 6.30 (0.84) | 6.13 (1.21) | 5.30 (0.87) |
| Hypogonadal | 18.12 (2.91) | 9.56 (2.29) | 11.19 (2.76) | 10.81 (2.92) | 12.06 (2.48) |
| <i>Confusion–bewilderment</i> | | | | | |
| Eugonadal-treated | 6.14 (0.97) | 5.32 (1.27) | 4.04 (0.95) | 3.57 (0.94) | 3.50 (0.87) |
| Eugonadal-placebo | 7.07 (1.11) | 5.73 (1.01) | 5.03 (0.78) | 4.87 (0.98) | 4.60 (0.98) |
| Hypogonadal | 12.25 (1.45) | 8.81 (1.16) | 8.75 (1.11) | 8.56 (1.61) | 8.44 (1.15) |

Standard error of means are given in parentheses.

[$F(4,136)=6.80$, $P<.01$], for depression–dejection [$F(4,136)=7.81$, $P<.01$], for fatigue–inertia [$F(4,136)=4.84$, $P<.01$], for confusion–bewilderment [$F(4,136)=11.96$, $P<.01$] but not for anger–hostility [$F(4,136)=0.79$, ns] or vigor–activity [$F(4,136)=1.54$, ns]. Significant main effects were found for group for tension–anxiety [$F(2,34)=10.83$, $P<.01$], for depression–dejection [$F(2,34)=10.70$, $P<.01$], for anger–hostility [$F(2,34)=27.03$, $P<.01$], for fatigue–inertia [$F(2,34)=8.49$, $P<.01$], for confusion–bewilderment [$F(2,34)=5.80$, $P<.01$] but not for vigor–activity [$F(2,34)=1.28$, ns]. The hypogonadal group reported significantly higher levels of tension–anxiety, depression–dejection, anger–hostility, fatigue–inertia, and confusion–bewilderment than the eugonadal men ($P<.01$). There was a significant Time \times Group interaction for tension–anxiety interaction [$F(8,136)=4.02$, $P<.01$], for anger–hostility [$F(8,136)=2.36$, $P<.05$], for vigor–activity [$F(8,136)=3.84$, $P<.01$], and for fatigue–inertia [$F(8,136)=3.02$, $P<.01$]. The Time \times Group interaction for depression–dejection [$F(8,136)=1.97$, $P=.08$] and for confusion–bewilderment [$F(8,136)=0.61$, ns] was not significant. Planned comparisons showed that significant reduction in tension–anxiety, anger–hostility, and fatigue–inertia by Weeks 1–2 and an increase in vigor–activity by Weeks 3–4 in the hypogonadal group explained the interaction effects, indicating a T treatment effect.

4. Discussion

We found that (trait) cognitive impulsivity (i.e. the tendency to make up one's mind quickly) and (trait) motor impulsivity (i.e. the tendency to act on impulse) accounted for significant amounts of the variance in total aggression levels, over and above age and level of T. This highlights the importance of including individual difference explanatory variables in experimental studies in this area. This finding adds support to an earlier study of violent and nonviolent male parolees by Cherek et al. [31]. They found that violent parolees scored significantly higher on a 'delayed gratification' impulsivity laboratory measure and on the BIS-11 compared to the nonviolent parolees. Furthermore, in another report using the same sample, Cherek et al. [32] found the number of impulsive choices chosen in all parolees to be significantly correlated with the number of aggressive responses reported previously.

Similarly, Galligani et al. [3] found in a study comparing AAS users with a drug-free group that the former reported levels of impulsiveness at least one standard deviation above the mean. The AAS users also reported significantly greater levels of indirect and verbal aggression. Another very recent study found impulsivity to predict AAS using group. That is, young men who report AAS use score significantly higher than non-AAS users [33] on impulsivity and self-reported aggression. Such data, taken as a whole suggest that an underlying mechanism, which inhibits

aggressive behavior, may be less effective, thus contributing to the aetiology of aggressive behavior in normal men. In other words, the link between steroid use and aggression may be that impulsive men are more likely to take steroids and also be aggressive.

However, given the methodological limitations of previous studies (i.e. overreliance of cross-sectional designs), it is difficult to decipher the exact nature of the relationship between impulsivity and aggressive behavior. Deficits in serotonin levels have been implicated in the development of both impulsive and aggressive behavior [34,35]. One recent study [35] found a significant reduction in impulsive responses in a sample of adult males with a history of conduct disorder after administration of D,L-fenfluramine—a drug which releases serotonin (and dopamine). Another found that laboratory aggressive responding increased following the ingestion of a tryptophan (a serotonin precursor)-depleting beverage supporting the notion that serotonin has a role in regulating aggression [36].

We also found that exogenous T administration did not lead to significant increases in a range of aggression measures in eugonadal men. This is not congruent with other experimental studies [15,16]. Most recently, Pope et al. [15] reported a significant increase in both aggressive responding as measured by the PSAP and ratings of manic symptoms. They suggested that the AQ may not be as sensitive as other aggression measures (cf. Ref. [37]) and that the Young Mania Rating Scale [38] and the PSAP were better adapted to detect T effects. This is a moot point given that an earlier paper by the authors [20] reported detecting T treatment effects using the AQ. Moreover, one would have predicted in the present study that our measure of irritability might have at the very least detected any real manic-like related changes. However, it is worth noting that when effect sizes were calculated for Weeks 0–4 comparisons, there were small effects in the direction of an increase in physical aggression. Although, nonsignificant these would need to be borne in mind for future meta-analyses since a series of nonsignificant findings that are all in the same direction may add up to a weak but significant effect when such studies are combined.

It is also reasonable to speculate that the subtle but significant adverse psychological effects reported elsewhere in the literature [16] are only associated with doses of T substantially higher than that employed in this study (>200 mg/week) or utilised in male contraception clinical trials. If this is the case, further high-dose studies are required using detailed self- and partner-reported behavioral and mood assessments in a double-blind, placebo-controlled, cross-over fashion.

We also failed to find any T-related mood effects in the eugonadal-treated group. However, the hypogonadals were identified as the group who benefited most from the T treatment. Significant reductions in tension, anger, and fatigue were reported by Weeks 1–2, followed by a significant increase in vigor by Weeks 3–4. There was also a trend towards a significant Time \times Group interaction for

state self-esteem levels, indicating a marked increase in levels of self-esteem in the hypogonadal group. These findings support earlier research that has found T administration to have positive mood effects when T levels are restored into the normal range [22,39] and suggest that prolonged treatment is likely to maintain these mood benefits, but not further improve them [40]. It is likely the marked elevations in self-esteem scores and positive mood states are concomitant with the restoration of normal sexual function as reported elsewhere [40]. Therefore, it is possible the changes in the psychological functioning are related to changes in sexual function.

The hypogonadal group generally reported significantly elevated levels of verbal aggression, hostility, anger, and irritability compared to both the eugonadal groups. We recognize that a hypogonadal–placebo group has not been included in the design of our study. Ethically and clinically, it would be problematic to treat hypogonadal men with a placebo in order to investigate behavioral changes. However, despite this, it is important to note that the ‘nonblinded’ hypogonadal group did not consistently report lower levels of aggression, hostility, anger, or irritability (comparable to both the eugonadal groups) after treatment commenced. Instead, their self-reported levels remained significantly higher, possibly indicating real concerns as opposed to a placebo effect. To the best of our knowledge, this is the first study to demonstrate the extent of the negative affect experienced by this patient population. These data have implications clinically, for both treatment and therapy.

In conclusion, we have found that supraphysiological levels of T do not lead to significantly increased aggression or mood disturbances. Instead, the inability to control one's behavior when such control is required by a particular situation was found to significantly predict levels of aggression over and above age and T level. Finally, our data for the first time have identified an unacceptably high level of negative affect experienced by hypogonadal patients before and during treatment that requires further investigation.

Acknowledgments

We are grateful to the World Health Organisation (Program No. 96374 to Wu and Archer) for funding this study, to Dr. Helen Buckler and Sister Marie Vickers (Hope Hospital, Manchester, UK) for assisting in the recruitment of hypogonadal patients, and to the Radioimmunoassay Laboratory personnel (Central Manchester Healthcare NHS Trust, UK) for T measurement.

AA2500 Testosterone Gel Normalizes Androgen Levels in Aging Males with Improvements in Body Composition and Sexual Function

C. STEIDLE, S. SCHWARTZ, K. JACOBY, T. SEBREE, T. SMITH, R. BACHAND, AND THE NORTH AMERICAN AA2500 T GEL STUDY GROUP

Northeast Indiana Research (C.S.), Fort Wayne, Indiana 46825; Diabetes and Glandular Disease Research Associates (S.S.), San Antonio, Texas 78229; Integrity Medical Research (K.J.), Seattle, Washington 98133; and Auxilium Pharmaceuticals, Inc. (T.Se., T.Sm., R.B.), Norristown, Pennsylvania 19041

Testosterone replacement in hypogonadal men improves body composition, mood, and sexual functioning. In this 90-d study, we compared the pharmacokinetics and treatment effectiveness of a topical testosterone gel (AA2500) at two concentrations, 50 mg/d and 100 mg/d, to a testosterone patch and placebo gel in 406 hypogonadal men. Pharmacokinetic profiles were obtained, body composition was measured, and mood and sexual function were monitored. AA2500 treatments resulted in dose-dependent improvements in all pharmacokinetic parameters, compared with testosterone patch and placebo. Mean average concentrations at d 90 T were 13.8, 17.1, 11.9, and 7.3 nmol/liter for 50 mg/d AA2500, 100 mg/d AA2500,

testosterone patch, and placebo, respectively. At d 90, the 100 mg/d AA2500 treatment improved lean body mass by 1.7 kg and percentage of body fat by 1.2% to a significantly greater degree than either control treatment. Significant improvements in spontaneous erections, sexual desire, and sexual motivation were also evidenced with the 100 mg/d AA2500 dose in comparison with placebo. Testosterone gel was well tolerated; however, the testosterone patch resulted in a high rate of application site reactions. Overall, AA2500 is an effective, well tolerated treatment for hypogonadism. (*J Clin Endocrinol Metab* 88: 2673–2681, 2003)

THE USE OF testosterone (T) replacement therapy in hypogonadal men has been well documented. Specifically, restoration of serum T concentrations to within normal limits (*i.e.* similar to that of eugonadal men) can maintain sexual characteristics, sexual behavior, energy, mood, and muscle development and improve bone density (1). Currently there are a number of different T dosage forms available for replacement therapy in hypogonadal men, but many of these formulations have limitations. Orally available T is relatively insoluble and subject to a high first-pass effect in the liver. Intramuscular depot injections are used widely for replacement therapy but are inconvenient and result in wide fluctuations in T levels. Specifically, high initial peak levels, followed by serum T levels below the lower limit of normal toward the end of the cycle, lead to a return of clinical signs and symptoms.

The skin and oral mucosa are considered favorable routes for the delivery of T. Transdermal T patches, including the scrotal patch (Testoderm), the nonscrotal permeation-enhanced patch with an alcohol-based reservoir (Androderm), and the nonscrotal patch without a reservoir (Testoderm TTS) provide a more consistent delivery of T into the systemic circulation, although serum T levels are not always

maintained within normal limits over a 24-h period. Long-term use of these patches (3–10 yr) has been shown to be effective in maintaining sexual function and bone and muscle mass in both young and elderly hypogonadal males (2–5); however, skin tolerability problems or the need for shaving large areas of scrotal skin invariably affect compliance with transdermal patches. Skin reactions commonly occur at the patch application site, particularly with the permeation-enhanced T patches causing erythema or pruritus. Blister reactions also occur leading to scarring and discontinuation of treatment (6, 7).

Previously, it has been reported that a T gel (AndroGel), when applied over a larger area of skin, can achieve serum T levels in the normal range and produce less skin irritation than T patches. A new, unique topical T gel formulation (AA2500) has been designed to provide consistent transdermal absorption of T over 24 h after a single dose and is hereby reported. Before this study, the pharmacokinetic (PK) profile of this new T gel (AA2500) was compared with AndroGel. Data have demonstrated that after topical application of a single dose of AA2500 T gel or AndroGel, the time to maximum concentration (T_{max}) was comparable between the two formulations indicating no appreciable differences in the rate of absorption. However, the 0- to 24-h area under the curve (AUC_{0-24}) and maximum concentration (C_{max}) were consistently higher following application of AA2500 with approximately 30% higher serum T levels being noted. The safety profile of these two topical gel formulations was similar (8).

The study reported here involves comparisons among four parallel treatment groups in 406 patients consisting primarily of aging males with low serum T and associated signs and

Abbreviations: AUC_{0-24} , 0- to 24-h Area under the curve; BPH, benign prostatic hyperplasia; C_{avg} , mean concentration; C_{max} , maximum concentration; C_{min} , minimum concentration; DHT, dihydrotestosterone; DRE, digital rectal examination; %F, percentage fat; FM, fat mass; HDL, high-density lipoprotein; I-PSS, International Prostate Symptom Score; LBM, lean body mass; LDL, low-density lipoprotein; PK, pharmacokinetic; PSA, prostate-specific antigen; T, testosterone; TBM, total body mass; TC, total cholesterol.

symptoms of hypogonadism. Two doses of AA2500 T gel (50 mg/d and 100 mg/d) were compared with a T patch treatment (Androderm, two patches delivering 5 mg T daily), a dose that is known to give rise to clinically meaningful increases in serum T levels with amelioration of signs and symptoms (9). The fourth parallel group was a matching placebo gel to provide a blinded comparator for the two doses of AA2500 T gel, which also provided a valid overall assessment of clinical and subjective symptom improvement. In this 90-d study, periodic 24-h PK profiles of total T and dihydrotestosterone (DHT) were obtained, and the effect of normalizing serum T on body composition, sexual function, mood, and bone mineral density were assessed. Routine safety evaluations were conducted, including skin irritation assessments at the study drug application site. As such, this study design was robust and unique in the assessment of the efficacy of topical transdermal T in normalizing serum T levels, ameliorating signs and symptoms of hypogonadism, and assessing its safety.

Subjects and Methods

Subjects

Four hundred six male patients were randomized and treated at 43 clinics in the United States. Approximately 100 patients were randomized to each treatment group (Table 1). Patients were between 20 and 80 yr of age and had a morning T level of 10.4 nmol/liter or less at screening (measured at a central laboratory) and one or more symptoms of low T (*i.e.* fatigue, decreased muscle mass, reduced libido, reduced sexual functioning of a nonmechanical nature). Except for hypogonadism, the patients were in generally good health as evidenced by medical history; complete physical examination including a digital rectal examination (DRE), 12-lead electrocardiogram, vital sign assessments, clinical laboratory and urinalysis assessments, prostate assessment [International Prostate Symptom Score (I-PSS)]; and normal tests for prostate-specific antigen (PSA), hepatitis, and drugs of abuse. If the patient was receiving lipid-lowering agents, anxiolytics, lithium, antidepressants, hypnotics, antipsychotics, α_1 blockers, or herbal treatments for benign prostatic hyperplasia (BPH), the dose had to have been stable for at least 3 months before entering the study. Patients were excluded from the study if they had any generalized skin irritation or disease that might have interfered with androgen absorption; had received any estrogen therapy, an LHRH antagonist, human GH therapy; or had a history of drug abuse within

12 months. Also excluded were patients who had used either Viagra or apomorphine within 30 d or were treated with T or anabolic supplements within 6 wk before the study. The study was conducted in accordance with the Declaration of Helsinki and complied with Good Clinical Practice, and all patients signed an informed consent agreement previously approved by one of the participating institutional review boards.

Study drugs

AA2500 T gel (Testim) was supplied by Auxilium Pharmaceuticals, Inc. (Norristown, PA). The four daily treatments under study were 50 mg/d AA2500 or 100 mg/d AA2500, matching placebo gel, and a transdermal T patch (Androderm, two patches \times 2.5 mg T), each containing 12.2 mg T. The AA2500 and placebo gel were identical and applied as two tubes of 50 mg T (100 mg/d), one tube of 50 mg T and one tube of placebo (50 mg/d), or two tubes of placebo. Neither the patients nor the investigators were aware of the contents of the tubes.

All study drug treatments were applied in the morning; repeat applications occurred at the same time of day for the duration of the study. Each day in the gel-treated group, patients applied the contents of two tubes. The content of one tube was applied to one shoulder and the content of the remaining tube was applied to the other shoulder. Patients allocated to receive the T patch applied two adhesive patches daily. Application sites included the back, abdomen, upper arms, and thighs. Patches were to be worn for 24 h and then replaced each morning at approximately the same time.

Study design

The study was designed as a randomized, multidose, multicenter, active, and placebo-controlled study. Patients were randomized to 50 mg AA2500 T gel (99 patients) or 100 mg AA2500 T gel (106 patients), matching placebo gel (99 patients), or T patch (102 patients). Randomization was performed to ensure an equal distribution of treatments across study centers. The study was double blinded for the AA2500 and placebo groups and open label for the T patch group. Patients randomized to one of the two AA2500 arms could be titrated at d 60 based on their d 30 T PK profile. Patients were titrated from 50 mg/d to 100 mg/d at d 60 if their d 30 mean serum T concentration (C_{avg}) was less than 10.4 nmol/liter (300 ng/dl). Patients were titrated from 100 mg/d to 50 mg/d at d 60 if their d 30 C_{avg} was more than 34.7 nmol/liter (1000 ng/dl). These titration decisions were undertaken by a third-party physician who was unaware of any clinical aspects of the individual patients and not otherwise involved in the study.

On d -1, patients had a baseline 24-h profile for serum T and DHT consisting of serum samples taken at 0800, 1000, and 1200 h, and 1600

TABLE 1. Subject characteristics

| | AA2500 | | T patch | Placebo | Total |

^a 0800 h serum concentration at screening examination.

^b Two subjects had a missing cause of hypogonadism.

^c Percentage of total by treatment group. Some subjects had more than one symptom, but all were required to have at least one. Distribution by cause is shown only if it occurred in $\geq 4\%$ of subjects.

and 0800 h on d 1, immediately before the first dose of study drug. On d 30 and 90, patients had a 24-h profile for T and DHT consisting of serum samples at predose and 2, 4, 8, 12, and 24 h after study drug administration. On d 60, a single 0800-h serum sample was taken for T and DHT. Blood samples for clinical laboratory assessment were collected at screening and on d -1, 30, 60, and 90. The prostate was evaluated at screening (PSA levels only) and d -1 and 90 with PSA levels, I-PSS, and DRE. Body composition [total body mass (TBM), lean body mass (LBM), and fat mass (FM)] and bone mineral density of the L1-L4 section of the lumbar spine were measured by dual energy x-ray absorptiometry on d -1 and d 90. Percentage fat (%F) was derived from FM and TBM. All body composition and bone mineral density measurements were centrally monitored and analyzed by Synarc, Inc. (Maynard, MA). Sexual function and mood questionnaires were recorded daily for 14 d before d 1 and daily for 7 d before d 30, 60, and 90. Data were collected centrally in real time via an interactive voice response system using the telephone. Skin irritation examination using a standardized, discrete scoring system was performed at d 1 (before dosing), 30, 60, and 90. Medical history and physical exams were completed, and all adverse events were recorded.

Methods

The skin irritation scoring was based on the following schema: 0, no erythema; 1, minimal erythema; 2, moderate erythema with sharply defined borders; 3, intense erythema with or without edema; 4, intense erythema with edema and blistering.

Sexual functioning and mood assessments were based on a questionnaire, one that had been validated for assessment of sexual function and mood and used previously in the evaluation of the effects of T gel on sexual function and mood (2). The questionnaire elicited information on sexual functions: performance, motivation, spontaneous erections, desire, enjoyment (with and without a partner), and satisfaction with erection duration and size. The sexual performance assessment was based on the following activities: orgasm, ejaculation, intercourse, masturbation, and erection in response to a sexual activity. The sexual performance score was the average number of days per 7-d week of these five activities. The sexual motivation assessment was based on the following activities: sexual daydreams, anticipation of sex, sexual interaction with partner, flirting by subject, and flirting by others toward subject. The sexual motivation score was the average number of days per 7-d week that these five activities occurred. The evaluation of spontaneous erections was the average number of days in a 7-d week that either spontaneous nighttime or daytime erections occurred. Sexual desire, sexual enjoyment, and satisfaction with erection were assessed on a Likert-type scale (score 0 to 7) and were calculated as average scores. Percentage of full erection was scored from 0% to 100%. Patients also rated positive mood (alert, full of energy, friendly, well or good) and negative mood (angry, irritable, sad or blue, tired, nervous) on a 0 to 7 categorical scale (0 = not at all true to 7 = very true). Average daily scores were computed.

Serum T and DHT levels were all measured at ICON Laboratories (Farmingdale, NY), using validated RIA kits. Kits (Diagnostic Products, Los Angeles, CA) were used for the T assays and kits obtained from Diagnostic Systems Laboratories, Inc. (Webster, TX) were used for DHT assays. The lower limits of detection for the T and DHT pharmacokinetic assays were 0.1 nmol/liter (4 ng/ml) and 0.01 nmol/liter (4 pg/ml), respectively. The DHT assay had a 0.02% or less cross-reactivity (after solvent extraction) with T and T had a 3.3% or less cross-reactivity with DHT up to 173.6 nmol/liter (5000 ng/dl). The mean accuracy (recovery) of T determined by spiking steroid-free serum with varying amounts of T [1.5–1.3 nmol/liter (44–36 ng/dl)] was 98% (range, 93–103). The intra- and interassay coefficients of the T assay were 6.7% and 7.9% for a control group adult male range of 8.5–63.8 nmol/liter (245–1836 ng/dl). The mean accuracy (recovery) of DHT determined by spiking steroid-free serum with various amounts of DHT [0.2–1.4 nmol/liter (59–418 pg/ml)] was 94% (range, 85–130). The intra- and interassay coefficients of the DHT assay were 4.6% and 6.4%, respectively, for a control group adult male range of 0.3–2.4 nmol/liter (97–711 pg/ml).

Statistical analyses

The 24-h PK profiles for T and DHT were summarized by C_{avg} (AUC_{0-24} divided by the 24-h sampling period, where AUC is cal-

culated using the trapezoidal rule), the minimum postdose concentration (C_{min}), and the postdose C_{max} . The changes from baseline to d 30 and d 90 in C_{min} , C_{avg} , and C_{max} were analyzed using an analysis of covariance with baseline value as the covariate and treatment group as the factor. Patients randomized to AA2500 (50 mg/d or 100 mg/d) may have had their dose changed at the d 60 visit. Those patients with a dose change will be analyzed at d 90 using the dose they received at the d 60 visit. Similar analyses were used for the change from baseline in sexual function, mood, and body composition as well as for the clinical laboratory parameters at d 30, 60, and 90. Treatment-emergent adverse events were compared using a Fisher's exact test. Skin irritation at d 30, 60, and 90 was analyzed using a Wilcoxon rank sum test. At d 30 and 90, the 50 mg/d and 100 mg/d AA2500 treatment groups were compared with T patch (PK parameters, sexual function, body composition, and mood) and placebo (sexual function, body composition, and mood). For each comparison, including safety parameters, an α -value of 0.05 was considered significant. The changes from baseline in sexual function, body composition, and mood were also analyzed for nonzero differences within each treatment group based on the adjusted least squares means from the analysis of covariance model. SAS version 6.12 (SAS Institute, Inc., Cary, NC) was used for all analyses. All data in tables are presented as means (\pm sd).

Results

Subjects

A total of 406 patients were randomized with 99, 106, 102, and 99 being randomized to the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo treatment groups, respectively (Table 1). Baseline patient characteristics (age, height, weight, body mass index, serum T at screening, I-PSS scores, and PSA levels) were comparable. Of the patients who had a valid PK profile, 70 of 399 (17.5%, 21 patients in 50 mg/d AA2500, 20 patients in 100 mg/d AA2500, 16 patients in T patch, and 13 patients in placebo groups) had a C_{avg} above 10.4 nmol/liter at baseline. Of these patients, 71% had at least one or more serum T measurement less than 10.4 nmol/liter during the course of d -1. Baseline mean C_{avg} serum T concentrations were 12.6, 12.1, 12.8, and 12.4 nmol/liter in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively. Fifty percent of the patients were aged 58 yr or older and approximately 26% were aged 65 yr and older with a mean age of 58 yr. Patient hypogonadism was primarily attributed to the secondary cause of aging and normogonadotrophic hypogonadism; these cases accounted for 91% of all causes in the overall population (Table 1). A significant proportion of enrolled patients completed the 90-d study (90% and 92% in the AA2500 and placebo groups, respectively, and 75% in the T patch group). The primary reason for the higher rate of discontinuations in the T patch group was adverse events (17%) with the majority of events being related to skin irritations at the patch site. Titrations made at d 60 in the AA2500 T gel groups were: 52 patients started on 50 mg/d dose and remained on 50 mg/d dose for the entire study, 43 patients who started on 50 mg/d dose were titrated up to the 100 mg/d dose, 93 patients who started on 100 mg/d dose remained at the 100 mg/d dose for the entire study, and 4 patients who started on 100 mg/d dose were titrated down to 50 mg/d dose. Patients who remained at 50 mg were more likely to have secondary hypogonadism, excluding aging, than patients who titrated to 100 mg. Dosing compliance ranged from 94.9% (placebo) to

97.1% (50 mg/d AA2500 and 100 mg/d AA2500 combined analysis).

T pharmacokinetics (Fig. 1 and Table 2)

At baseline, mean C_{avg} serum T concentrations were below the normal adult range (10.4–34.7 nmol/liter) and similar across treatment groups. By d 30, the mean C_{avg} for the 50 mg/d AA2500 treatment had increased 50% over baseline with a similar increase being evidenced in the T patch treatment group. The 100 mg/d AA2500 dose resulted in a 173% increase with a significant difference ($P < 0.001$) in comparison with the T patch treatment group. The C_{avg} was increased above 10.4 nmol/liter in 55% of 50 mg/d AA2500 patients, 95% of the 100 mg/d AA2500 patients, 68% of the T patch patients, and 8% of the placebo patients. In the 100

mg/d AA2500 group, 30 patients had a C_{max} higher than the upper limit of normal (34.7 nmol/liter), but 26 of these patients had a C_{avg} still between 10.4–34.7 nmol/liter. The degree of fluctuation during a day in serum values [$(C_{max} - C_{min})/C_{avg}$] was significantly smaller in the two AA2500 dose groups in comparison with the T patch group. By d 90, similar results were seen across the treatment groups. Approximately 75% of 50 mg/d AA2500 and 80% of 100 mg/d AA2500 treated patients had C_{avg} values above 10.4 nmol/liter, in comparison with 57% of the T patch-treated patients and 10% of placebo-treated patients.

DHT pharmacokinetics (Fig. 2 and Table 3)

At baseline, mean C_{avg} serum DHT concentrations were below the normal adult male range (0.9–2.6 nmol/liter) and similar across treatment groups. Mean changes in DHT C_{avg} from baseline to d 30 for the 50 mg/d AA2500 and 100 mg/d AA2500 dose groups were more than 4- and 7-fold greater, respectively, than changes observed in the T patch treatment group ($P < 0.001$ for each comparison). Similar to C_{avg} , C_{min} results further demonstrated the effectiveness of both AA2500 doses in increasing the d 30 C_{min} to a significantly greater degree than the T patch treatment ($P < 0.001$ for each comparison). The 100 mg/d AA2500 dose achieved a mean d 30 C_{min} that was within the normal range. For C_{max} , the d 30 effects reported were similar to that observed with C_{avg} . The C_{max} mean changes in serum DHT from baseline to d 30 for both AA2500 dose groups were approximately 4- and 7-fold greater than that evidenced in the T patch group ($P < 0.001$ for each comparison) with 15 (16%), 39 (42%), 1 (1%), and no patients in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively, exceeding the normal range. At d 30, examination of the DHT to T C_{avg} ratio demonstrated that this ratio was not altered by either the T patch or placebo treatment, whereas a near doubling of the ratio was, respectively, evidenced with both AA2500 doses. By d 90, similar results were seen across the treatment groups. Additionally, the higher serum levels of DHT obtained with the AA2500 treatments correlated with the serum T levels obtained.

Body composition (Fig. 3)

At baseline, there were no significant differences in LBM, FM, %F, and TBM among the four treatment groups. At d 90, the 100 mg/d AA2500 treatment increased LBM to a significantly greater degree than the T patch or placebo treatment ($P < 0.05$ for each comparison) with mean changes from baseline of 1.5 ± 4.5 , 1.7 ± 2.6 , 0.9 ± 1.8 , and 0.6 ± 1.8 kg for the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo treatment groups, respectively. With the exception of placebo treatment, all treatments resulted in a decrease in FM, which were significant, compared with placebo ($P < 0.01$). Reductions of 0.8 ± 2.4 , 0.8 ± 2.0 , 0.4 ± 1.8 , and 0.1 ± 1.5 kg were noted in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo treatment groups, respectively. Reductions in %F were evidenced in all treatment groups, with the AA2500 treatments yielding the most notable decreases. Specifically, at d 90, the 50 mg/d AA2500 dose resulted in a reduction of $1.1 \pm 3.2\%$ which was sig-

FIG. 1. Serum T concentrations before (baseline) and after study drug treatment on d 30 and 90. Time 0 was approximately 0800 h. Solid horizontal lines denote the adult male range (10.4–34.7 nmol/liter). ●, 50 mg/d AA2500; ■, 100 mg/d AA2500; ○, T patch; ◇, placebo.

| | | Actual | 8.7 ± 3.9 ^b | 10.9 ± 6.0 ^b | 5.7 ± 2.8 |
| | C _{max} | Baseline | 11.3 ± 4.1 | 9.8 ± 2.9 | 10.3 ± 3.7 |
| | | Actual | 19.5 ± 12.2 | 24.4 ± 13.8 ^b | 18.5 ± 8.2 |

Values are expressed as means ± 1 SD. Change from baseline significant vs. T patch: ^a $P < 0.05$, ^b $P < 0.001$.

nificant in comparison to the reduction evidenced with placebo treatment ($0.2 \pm 1.4\%$, $P < 0.05$). Furthermore, the 100 mg/d AA2500 treatment resulted in a $1.2 \pm 1.9\%$ reduction at d 90, which was not only significant in comparison with placebo ($P < 0.01$) but also significant in comparison with the T patch treatment ($0.5 \pm 1.6\%$, $P < 0.05$). Although all treatments resulted in minimal increases in TBM, no significant differences were noted among the treatment groups.

Mood and sexual function (Table 4)

Although all treatments resulted in mean improvements from baseline in both positive and negative mood scores, no significant differences among the treatment groups were observed.

At baseline, sexual function scores were similar across the four treatment groups. Evaluation of the mean data demonstrated that the 100 mg/d AA2500 dose showed a significant improvement at d 90 over placebo treatment for spontaneous erections ($P < 0.001$), sexual motivation ($P < 0.05$), sexual desire ($P < 0.01$), and sexual performance ($P < 0.05$). Furthermore, the improvement from baseline was also significant for these parameters.

All other measures of sexual function (e.g. sexual enjoyment with a partner, sexual enjoyment without a partner, satisfaction with erection duration, and percentage of full erection) showed no significant difference in improvement between treatment groups.

Safety

Adverse events. The incidence of treatment-related adverse events was 29.1%, 36.9%, 62.7%, and 40.4% in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively. Although treatment in the AA2500 and placebo groups was relatively well tolerated over the 90-d study period, the T patch-treated patients experienced a substantially higher rate of adverse events. Those most commonly seen were application site erythema, application site rash, application site pruritus, application site reactions, and application site irritation.

Specific events that were possibly or probably related to study drug and reported by 1% or more of the AA2500

patients and greater than placebo included application site reactions, BPH, increases in blood pressure and hematocrit/hemoglobin, gynecomastia, headache, hot flushes, insomnia, increased lacrimation, mood swings, smell and taste disorders, and spontaneous penile erections.

Only six patients in AA2500 treatment groups experienced adverse events that led to discontinuation. Specific events in the 100 mg/d AA2500 treatment group included vertigo, coronary artery disease, depression with suicidal ideation, urinary tract infection/pneumonia, and hypertension. All events with the exception of hypertension were considered unrelated to treatment. Mood swings, considered related to treatment, was the only event in the 50 mg/d AA2500 treatment group that led to discontinuation. Lastly, no patients in the 50 mg/d or 100 mg/d AA2500 treatment groups discontinued because of skin reaction, whereas the majority of patients that discontinued in the T patch group did so as a result of local dermal site reactions ($n = 15$).

With regard to prostate-related events, mild BPH was reported in two patients in the 100 mg/d AA2500 treatment group and one patient in the placebo treatment group. Additionally, two T patch-treated patients were diagnosed with prostatic cancer.

Laboratory analyses

Statistically significant differences between the 50 mg/d and/or 100 mg/d AA2500 groups and placebo groups in serum blood urea nitrogen (-2.0 ± 4.0 , -1.7 ± 4.3 , and -0.6 ± 3.9 mg/dl, respectively), creatinine (0.04 ± 0.12 , 0.07 ± 0.14 , and -0.02 ± 0.12 mg/dl, respectively), and fasting glucose levels (-2.2 ± 18.1 , -5.6 ± 25.1 , and 4.0 ± 25.3 mg/dl, respectively) were observed; however, these differences were minor and not clinically meaningful.

At d 90, clinically notable decreases from baseline in average total cholesterol (TC), low-density lipoproteins (LDL), and high-density lipoproteins (HDL) were evidenced with the 100 mg/d AA2500 group (-7% , -7% , and -8% , respectively). Mean d 90 LDL/HDL ratios (2.73, 2.56, 2.52, and 2.41 for the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively) remained essentially unchanged from baseline. Additionally, mean d 90 HDL/TC

FIG. 2. Serum DHT concentrations before (baseline) and after study drug treatment on d 30 and 90. Time 0 was approximately 0800 h. Solid horizontal lines denote the adult male range (0.8–2.6 nmol/liter). ●, 50 mg/d AA2500; ■, 100 mg/d AA2500; ○, T patch; ◇, placebo.

ratios (0.23, 0.24, 0.24, and 0.24 for the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively) also remained unchanged.

Increases in hemoglobin and hematocrit are known pharmacological class effects of T. Consistent with this, patients in the 50 mg/d and 100 mg/d AA2500 group experienced statistically significant mean d 90 increases in hematocrit and hemoglobin of $2.3 \pm 3.4\%$ and 0.96 ± 0.96 g/dl, respectively, in the 50 mg/d AA2500 group and $2.8 \pm 3.5\%$ and 0.94 ± 1.06 g/dl in the 100 mg/d AA2500 group, compared with the placebo treatment group ($-0.1 \pm 2.8\%$ and 0.12 ± 0.71 g/dl) and T patch treatment group ($1.1 \pm 2.6\%$ and 0.48 ± 0.74 g/dl). The effects observed with T patch treatment were consistently greater than observed with placebo treatment

but less than those observed with the AA2500 treatments, reflecting the lower average serum T levels associated with the T patch treatment. At d 30 and 60, similar effects were reported for the AA2500 treatment group. Overall, approximately 3%, 6%, 1%, and 1% of patients in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively, experienced a hematocrit value more than 55% at least once during the study. Statistically significant mean changes were also reported for lymphocytes and monocytes, but the changes were small and not of apparent clinical significance.

PSA values (Table 5) more than 4.0 ng/ml were noted at least once during treatment in 1.8%, 2.9%, 6.6%, and 3.2% of patients in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo treatment groups, respectively. PSA elevations were noted in all groups with the T patch group evidencing the greatest number of transient and persistent elevations. Mean changes from baseline to d 90 of 0.3 ± 1.8 , 0.1 ± 0.4 , 0.2 ± 0.6 , and -0.1 ± 0.4 ng/ml for the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo treatment groups, respectively. Of note, one patient in the 50 mg/d AA2500 treatment group experienced a transient elevation of 17.6 ng/ml (without clinically valid explanation) that upon repeat evaluation returned to normal (3.6 ng/ml).

The changes from baseline for I-PSS were small, and the incidence of patients experiencing a general worsening of their DRE was low (3.4%, 1.4%, 0%, and 4.2% in the 50 mg/d AA2500, 100 mg/d AA2500, T patch, and placebo groups, respectively). Both parameters provided no evidence of clinically relevant treatment-related effects or differences.

Skin irritation (Fig. 4)

Figure 4 provides a graphic illustration of the frequency distribution of patients having positive skin irritation scores. It can be seen that the events occurred predominantly in the T patch treatment group and only a few mild reactions occurred in the combined AA2500 and placebo treatment groups. Additionally, the figure illustrates that the T patch acted as an irritant in some patients who experienced classic signs of contact dermatitis and that the AA2500 treatments were no more irritating than the placebo gel vehicle from d 60 through the completion of the study.

Discussion

This study demonstrated that this new, unique T gel (AA2500), when titrated to clinical effectiveness, was superior to the T patch in normalizing serum T in patients with hypogonadism. Specifically, the 100 mg/d dose was not only effective in significantly improving sexual performance, sexual motivation, and sexual desire and increasing spontaneous erections but also increasing LBM and decreasing FM and %F. There were associated increases in hemoglobin and hematocrit, which are known pharmacological class effects of T administration. The small mean increases in PSA observed with AA2500 doses and the T patch treatment groups, but not the placebo group, were not associated with an increase in I-PSS. Small decreases in TC, LDL, and HDL were observed in the AA2500 treatment groups with no changes in HDL/TC or LDL/HDL ratios. Erythema, rash, pruritus,

doses of AA2500 also resulted in a significantly greater decrease in FM and %F, compared with placebo. Normalization of serum T levels were achieved with both doses of AA2500 for average T levels and minimum T levels over a 24-h dosing period. In contrast, the T patch group was able to restore only average T levels. Previously reported data suggest that increases in LBM and decreases in FM are correlated with serum T levels (1). This difference in normalization may explain the greater increase in LBM and greater decrease in FM and %F observed with the AA2500 treatments. In previous studies in hypogonadal men, T replacement therapy has resulted in decreases in FM in some studies using injectable or transdermal T but not in other studies in which

either injectable or sublingual T has been administered. The difference in results observed in these previous reports might be due to lower serum T levels achieved by different T preparations.

Regarding DHT, although it is true that the AA2500 treatments produced higher serum levels at d 30 and 90, the DHT/T ratio remained stable and similar to that reported in normal men, demonstrating concordance with the naturally occurring 5 α -reductase conversion of T to DHT. The effect of serum DHT levels on the intraprostatic levels of DHT is not known. As with serum T levels, a prospective relationship between DHT serum levels and the incidence of prostate cancer has not been demonstrated (10, 11). Further long-term studies are needed to clarify the effect of increased DHT on the prostate.

There were no unexpectedly abnormal laboratory values and the incidence of clinically relevant abnormal findings was low. By d 90, patients in the AA2500 group who were administered 50 mg/d or 100 mg/d experienced statistically significant increases in hematocrit and hemoglobin, compared with patients receiving T patch or placebo. The increases observed in the T patch group were consistently greater than those observed in the placebo group but less than those observed in the AA2500 groups. This is likely a result of the lower serum T levels achieved with T patch. A previous study demonstrated similar increases in hematocrit and hemoglobin with T replacement therapy, with these increases being more marked with higher doses of T (1). These small increases in hematocrit and hemoglobin, which can occur with T replacement therapy, may even be beneficial in hypogonadal patients in whom anemia, lethargy, and fatigue are commonly found; however, a small percentage of treated individuals may increase their hematocrit levels to more than 55% and in turn be prone to the problems

associated with polycythemia. To this end, periodic monitoring of hematocrit is recommended to determine whether T therapy dose adjustments or termination (*i.e.* in the event hematocrit values do not fall below 55%) may be required.

Small increases in PSA similar to those seen in previous studies with T replacement therapy were observed in both AA2500 groups and in the T patch group. However, the magnitude of the increase in PSA, changes in I-PSS, and findings from DRE following treatment with either dose of AA2500 or T patch in this study were not of clinical concern. Although T has not been shown to induce cancer of the prostate, two patients on the T patch were diagnosed with prostate cancer during the study. This is not surprising because elderly men are at an increased risk of developing prostate cancer and the diagnosis can be made as a result of an elevated PSA subsequently leading to prostatic biopsy.

Very few adverse effects were reported following topical application of AA2500, and those that were reported were similar in type to the known class effects of T. Of particular note was the very low incidence of skin irritation reported with AA2500, which was comparable to placebo and significantly lower than T patch. Furthermore, no patient in the gel groups discontinued because of skin intolerance.

This study clearly shows that 100 mg/d AA2500 dose is superior to T patch in normalizing serum T and DHT in hypogonadal men. The AA2500 treatments resulted in increasing LBM (100 mg/d dose) and decreasing FM and %F to a greater degree than either the T patch or placebo. Furthermore, significant improvements from baseline and in comparison to placebo were observed for spontaneous erections, sexual motivation, sexual desire, and sexual performance with 100 mg/d AA2500 dose. Overall, this new, unique T gel (AA2500) can offer benefit over other transdermal preparations because of improved 24-h serum T levels and improved compliance as a result of a lower incidence of local dermal irritation.

Detection of anabolic steroid administration: ratio of urinary testosterone to epitestosterone vs the ratio of urinary testosterone to luteinizing hormone

PAUL J. PERRY,^{1,3*} JOHN H. MACINDOE,² WILLIAM R. YATES,¹ SHANE D. SCOTT,³ and
TIMOTHY L. HOLMAN¹

Our goal in this study was to determine whether the urinary ratio of testosterone to luteinizing hormone (T/LH) as an indicator of exogenous anabolic steroid (AS) use is superior to the urinary ratio of testosterone to epitestosterone (T/E). After 2 weekly placebo injections, 19 subjects were given testosterone cypionate (TC) injections of 250 or 500 mg/week for 14 weeks followed by 14 weekly placebo injections. Patients were considered to have ceased taking TC if they tested negative 9 weeks after their last injection. For detection of illicit or supraphysiological TC (AS) use, the urinary T/E ratio of ≥ 6 yielded a false-negative rate of 46% and a false-positive rate of 4%. However, a urinary T/LH ratio of ≥ 30 produced a false-negative rate of only 24% and a false-positive rate of 13%. We conclude that the urinary T/LH ratio of ≥ 30 is a more sensitive marker of AS use than the urinary T/E ratio of ≥ 6 and remains sensitive for twice as long as urinary T/E.

INDEXING TERMS: abused drugs • sports medicine • GC-MS • androgens • anabolic steroids

The primary method for detecting illicit anabolic steroid (AS) use has been the analysis of urinary steroids.⁴ This methodology has been successful for the majority of steroids, especially the synthetic variety that have specific

structures that are easily identified by GC-MS. However, the detection and monitoring of anabolic compounds is not fail-safe. Detection of the illicit use of testosterone (T), a naturally occurring AS, has become a difficult clinical problem. Methods for detecting administration of exogenous T depend on distortions of the normal hormone profile in the user's urine [1]. Attempts to identify optimal markers of exogenous T administration from untimed urine samples in male athletes have uncovered several compounds as possible indicators of T abuse. In 1982, the ratio of androgen glucuronides to epitestosterone (E; 17 α -hydroxy-4-androsten-3-one) was adopted by the Medical Commission of the International Olympic Committee (IOC) in Los Angeles, with a cutoff point ≥ 6 being the sole test for illicit T self-administration [2, 3]; the expected urinary ratio of T/E among healthy subjects not using AS is ~ 1 [1]. However, analyses from all IOC-accredited laboratories in 1991 suggested that the majority of athletes who were using AS had switched from synthetic compounds to T pharmaceuticals to evade detection [4]. Consequently, covert AS use has become more difficult to detect.

The overall incidence of urinary T/E ≥ 6 in the general population of healthy males not abusing steroids is $<0.8\%$, as evaluated by Catlin and Hatton [5] and confirmed by Dehennin [4]. In general, the increase of the T/E ratio after high-dose T administration results from increased T excretion and a decrease of E output [6]. However, some athletes have produced false-positives, i.e., T/E ratios ≥ 6 with subsequent verification that no exogenous T had been administered [7]. Dehennin and Matsumoto [6] indicated that this problem could be reduced by taking into account the sulfate excretions of E (ES) in the ratio T/(ES + E), the relevant threshold being 2.85. Accordingly, Dehennin [4] suggested that using a

⁴ Nonstandard abbreviations: AS, anabolic steroid(s); T, testosterone; E, epitestosterone; IOC, International Olympics Committee; ES, epitestosterone sulfate; LH, luteinizing hormone; and TC, testosterone cypionate.

Received September 10, 1996; revised December 3, 1996; accepted December 20, 1996.

T/(ES + E) ratio of ≥ 3.0 would be a more sensitive marker of covert T use.

Dehennin [7] also noted that the joint misuse of T and E could also lead to false-negative test results, and the IOC in 1992 recommended that urinary E concentrations >150 $\mu\text{g/L}$ should be noted as abnormally high and therefore suspicious. False-negative results can also be produced by stimulation of testicular steroidogenesis by administering human chorionic gonadotropin, which would result in a concomitant increase in the urinary excretion rate of T and E but with no significant change in the T/E ratio [1]. Dehennin and Matsumoto [6] confirmed earlier reports of false negatives by demonstrating that, despite their determination that an average dose of 47 mg of exogenous testosterone per week would equal or exceed the IOC cutoff, 2 of 9 subjects receiving 72 mg of testosterone (100 mg of testosterone enanthate) per week for 6 months did not produce a T/E ratio ≥ 6 .

Dehennin [4] suggested that when a T/E ratio of 6 to 12 is found for the first time in subjects for whom no documentation of a previously normal ratio exists, some complimentary criteria should be examined. He found that the ratio of urinary T and E glucuronides to 5-androstene-3 β ,17 α -diol glucuronide was increased in the use of exogenous T and E use despite the T/E ratio being <6 . These findings indicate a need for further study of additional markers for detecting the administration of T.

Because the secretion of T is under the control of luteinizing hormone (LH), Brooks et al. [8] suggested that the urinary T/LH ratio might be a potentially useful marker for detecting administration of exogenous T. Kicman et al. [9] observed that high-dose T administration resulted in dose-dependent suppression of both serum and urinary LH. This was confirmed by Matsumoto [2], who found that the urinary LH excretion was reduced to a lesser extent than was the decrease in both E and T conjugates, such that the T/LH values were lower than those reported by Kicman et al.—also suggesting a need for more study.

Palonek et al. [3] reported significantly increased T/LH ratios in 11 healthy sedentary men participating in a WHO investigational program for male contraception. Each subject received 144 mg of T per week (200 mg of testosterone enanthate) for 9 months. The T/LH ratio increased from a mean of 0.052 (range 0.002–0.108) at baseline to 45.16 (1.28–252) at 3 months, 85.7 (8.3–238) at 6 months, and 71.7 (5.3–344) at 9 months. The authors indicated that, among all the different ratios or proposed markers they investigated, the urinary T/LH ratio showed the most dramatic increase (~ 1000 -fold). Of the other markers, the increase in the serum T/LH ratio was of similar magnitude as that of the urinary T/LH ratio, whereas the urinary T/E ratio had only a 50-fold increase. The investigators also reported that 1 of the 11 subjects produced a T/E ratio below the IOC cutoff at 3 and 9 months of administration and just over the threshold at 6 months. The T/LH ratio for the same subject was above

the upper reference limit at 3, 6, and 9 months. Palonek et al. concluded that increased serum and urinary T/LH ratios in the presence of a normal T/E ratio may indicate self-administration of both T and E.

Unanswered is whether the T/LH ratio might be more sensitive than the T/E ratio for identifying illicit use of AS. Thus the goal of the present study was to determine which laboratory test is most sensitive and specific for detecting the administration of exogenous T.

Materials and Methods

SUBJECTS AND STUDY DESIGN

Healthy male volunteers between ages 18 and 40 years were recruited and, after an explanation of the study, gave their signed informed consent. The study protocol was reviewed and approved by the Human Subjects Institutional Review Board and the Clinic Research Center of the University of Iowa. A standard drug history, developed by the National Institute on Drug Abuse, was administered before entry. Any subject who indicated he was currently using central nervous system stimulants other than modest amounts of caffeine (two cups of coffee per day) was excluded from the study.

Each subject received two weekly placebo doses of cottonseed oil, the vehicle for testosterone cypionate (TC). At the end of the 2-week placebo lead-in period, subjects were randomized to one of three doses of TC (100, 250, or 500 mg/week) given for 14 consecutive weeks. In our experience with AS users [10], the subjects' shortest average cycle was 7 weeks, the longest 14 weeks. Thus, we decided that subjects should be administered TC for a typical 14-week AS cycle to mimic the maximum cycling interval.

Subjects functioned as their own controls. They received weekly intramuscular injections of either TC or placebo (vehicle only) for 28 consecutive weeks. For the purpose of evaluating the effectiveness of the urine T/E ratio as an indicator of recent AS use, we considered only the subjects receiving supraphysiological TC doses (250 and 500 mg/week). A 100 mg/week dose is generally regarded as a physiological replacement dose in the majority of patients.

To monitor the subjects medically, we assessed their liver-function tests, fasting lipid profiles, thyroxine-binding globulin, sex-hormone-binding globulin, 24-h urinary free cortisols, serum free and total T, estradiol, LH, follicle-stimulating hormone, thyroid-stimulating hormone, and free thyroxine—obtained at baseline, at entry into the study, after the 2-week placebo injection period, and then biweekly for the remainder of the study. All endocrine samples were collected between 0700 and 0900 to minimize the chronotropic secretion effects of these hormones. Depo[®]-testosterone (TC), 200 g/L (200 mg/mL), was the proprietary product utilized for the study. The diluent (0.2 mL of benzyl benzoate, 9.45 mg of benzyl alcohol, and 560 mg of cottonseed oil per milliliter) was prepared by the Pharmaceutical Services Division of the

University of Iowa College of Pharmacy (an FDA-approved manufacturing group). At the end of the 14 weeks of TC administration, the subjects were switched to diluent-only injections.

ASSAYS

The urine drug screens were performed by Smith Kline Beecham Clinical Laboratories Sports Testing Center in Tucker, GA, a laboratory certified by the US Department of Health and Human Services. The initial drug screen and all subsequent screens were negative for AS (other than T), amphetamines, barbiturates, benzodiazepines, cocaine metabolites, methadone, methaqualone, opiates, phenylclidine, and propoxyphene.

Urine concentrations of T, E, LH, and creatinine were also determined in the samples (assayed by Smith Kline Beecham). The urine samples were refrigerated at 8 °C and were analyzed within 5–10 days after collection. If the T/E ratio was <6, the sample was discarded within 30 days. Urine drug screens were routinely obtained at weeks 0, 1, 4, 8, 12, 16 or 17, 20, 24, and 28; in some follow-up cases, they were obtained at weeks 40 and 92. AS screens and confirmations were performed by GC-MS on separate aliquots. Samples were initially screened for the substance abuse panel by Emit (Behring, Palo Alto, CA); all positive results were confirmed by GC-MS [11]. LH in urine was performed by Microparticle Enzyme Immunoassay with the Abbott Diagnostics (Chicago, IL) IMx system.

The T/E ratio was determined by GC-MS. Both free and conjugated T and E were extracted with C₁₈ solid-phase extraction columns (Bond Elute LRC; Varian, Harbor City, CA), hydrolyzed with β -glucuronidase (Boehringer Mannheim, Mannheim, Germany), and detected by monitoring characteristic ions with the mass spectrometer. Quantification and identification of T and E required selected-ion mode analysis in which the presumptive positive specimens were matched with the retention times and ion ratios of known compounds. The T calibration curve was linear between 2 and 400 μ g/L; that for E was linear between 2 and 500 μ g/L. The CV for the T/E ratio was 13.3%. The specificity of this method is extremely high: At the time of the performance of the assays, no compounds were known to interfere with either T or E.

The urine concentration of LH was determined with the IMx system kit for serum LH as described in the 1991 IMx LH package insert. To determine that there was no matrix effect for the assay, we added known amounts LH to urine and serum samples and found that the resulting calibration curves could be superimposed on each other and were linear between 2 and 600 IU/L. The lower limit of detection for this assay is 0.5 IU/L. The CV for the serum LH assay is 8.7% at 5.37 IU/L, 6.4% at 43.2 IU/L, and 6.2% at 82.5 IU/L.

All serum samples for determining free and total T were stored at -20 °C until assay. The T concentrations were quantified with Coat-A-Count® kits (Diagnostic

Products Corp., Los Angeles, CA) as described in the manufacturer's package insert (1995). The lower limits of detection were 40 ng/L for total T and 0.15 ng/L for free T. The inter- and intraassay CVs for the free T assay were 11.2% and 5.5%, respectively; those for total T were 10.4% and 8.8%, respectively.

Results

In all, 93 urine drug screen samples were obtained from the 19 subjects participating in the study who received supraphysiological doses of TC. Seven received 250 mg/week and 12 took 500 mg/week. None of the subjects was positive for exogenous AS use other than for the TC injections administered during weeks 2–15 of the study. Concentrations of free T in serum were analyzed 5–7 times between days 3 and 21 after the last TC injection for 17 of the 19 subjects. From these data, we calculated for each patient the terminal elimination rate (k_e) and the elimination half-life ($t_{1/2}$) for free T in serum. To determine k_e , we fit the T concentrations $f(t)$ and time points (t) to the following single exponential decay equation, where a is the concentration of T at time 0:

$$f(t) = ae^{-k_e t} \quad (1)$$

We determined $t_{1/2}$ as follows:

$$t_{1/2} = 0.693/k_e \quad (2)$$

A 21-day T sampling period was appropriate to determine the $t_{1/2}$ of exogenous T because gonadotropin-releasing-hormone stimulation tests indicated that the hypothalamic-pituitary-testicular axes of the subjects did not regain sufficient sensitivity to stimulate release of T until 4–6 weeks after discontinuation of the TC injections.

Table 1. Elimination half-life of free testosterone in 19 subjects.

| Subject | TC dose, mg/week | Free T elimination half-life, days |

The individual elimination half-life data are presented in Table 1. There was no difference in half-life values between the weekly TC doses of 250 and 500 mg (Mann-Whitney $U = 25.0$, $P = 0.37$). The overall mean \pm SD elimination half-life for free T in serum after administration of TC was 6.6 ± 2.3 days. Based on these data, an 11-day $t_{1/2}$ would be 2 SD from the mean. Given that 97% of the exogenous T was excreted in 5 half-lives (i.e., 11-day half-life \times 5 half-lives = 55 days, or 8 weeks) and that pituitary sensitivity to gonadotropin-releasing hormone returned within 4–6 weeks of the last TC injection, subjects were assumed to have ceased taking ("be off") exogenous T by the time of the urine drug screen performed 9 weeks after the last TC injection.

The AS urine drug screen findings indicated that the urinary T/E ratio cutoff of ≥ 6 , the traditional laboratory marker to determine the use of exogenous T and used as such by the National Collegiate Athletic Association and the IOC, although quite specific for determining nonuse of T, is not a sensitive indicator for detecting illicit T usage. Table 2 illustrates this. Although the T/E ratio of >6 had 96% specificity in identifying our subjects as being off steroids by 9 weeks after their last dose, it was correct only 54% of the time for identifying our subjects as being on steroids during the 14 weeks of TC injections and in the 9 subsequent weeks when they received sham injections. As a practical matter, these data suggest that one of every two subjects using injectable TC will, both during injection periods and for 9 weeks afterwards, give a false-negative urine drug screen. Receiver operating characteristic (ROC) analysis of these data [12] identified a urinary T/E ratio of ≥ 1.2 as the cutoff value that provided optimum sensitivity and specificity for indicating use or nonuse of T. Resorting the data in Table 2 illustrates that use of a T/E ratio of ≥ 1.2 for a T-positive urine improves the sensitivity to 83% and the specificity decreases only somewhat, to 77%.

The potential usefulness of the urine T/LH ratio as an indicator of T use and nonuse is illustrated in Table 3. These data suggest that to maintain 100% specificity requires a threshold T/LH ratio of ≥ 74 , although the sensitivity at this cutoff is only 52%. However, by ROC analysis (data not shown), the urinary T/LH ratio cut-

| T/LH ratio | No. of subjects | |
|-------------|-----------------|---------------------|
| | On TC | Off TC ^a |
| $\geq 74^b$ | 24 | 0 |
| $< 74^b$ | 22 | 47 |
| $\geq 30^c$ | 35 | 6 |
| $< 30^c$ | 11 | 41 |

^a Subjects who tested negative 9 weeks after their last TC injection.

^b $\chi^2 = 33.051$, $P < 0.0001$, sensitivity = 52%, specificity = 100%.

^c $\chi^2 = 37.814$, $P < 0.0001$, sensitivity = 76%, and specificity = 87%.

point that optimizes sensitivity and specificity is ≥ 30 . As Table 3 shows, use of a urinary T/LH ratio ≥ 30 increases sensitivity to 76% but decreases specificity to 87%.

Discussion

From a medical-legal standpoint the most worrisome finding of these data is the false-positive tests. Table 4 characterizes the false positives—i.e., a test result that is not negative at 9 weeks after the last TC injection—for the various testing schemes. Nine weeks is equivalent to the amount of time required to clear 97% of the exogenous TC. For the urinary T/E ratio of 6, only two subjects did not meet this criteria, whereas for the urine T/LH ratio of 30, four subjects did not meet this criteria. All six patients who tested "positive" were actually tested 9–25 weeks after their last TC injection. When contrasted with the half-life data, this suggests that the normalization of LH concentrations may lag behind the rate at which the exogenous T clears from the body. Moreover, in reality there are no truly false-positive test results. However, in no case did a subject's urine screen test positive before the start of the TC injections.

The mean \pm SD urinary T/LH and T/E ratios before the start of the TC injections were 3.8 ± 2.4 and 0.8 ± 1.3 , respectively. Other than when the subjects were receiving T injections, the only time there was a significant difference between pre-TC injection urinary T/E and T/LH ratios and the ratios after the start of the TC injections was 2 weeks after the last injection. For the urinary T/LH ratio, the mean difference between the baseline value and the ratio 2 weeks after the last injection was 29.8 ($t = 2.829$, $P < 0.02$, $df = 16$); for the urine T/E ratio, the mean difference was 14.9 ($t = 2.703$, $P < 0.02$, $df = 16$).

As suggested in Table 4, the urinary T/LH ratio of ≥ 30 is the screen most likely to detect AS use the longest, i.e., as long as 25 weeks after the last injection. Using the urinary T/LH ratio ≥ 30 as a marker showed that 4 of 19 (21%) subjects tested positive 9–25 weeks after their last injection of T. In contrast, use of the urinary T/E ratio ≥ 6 found only 2 of 19 (11%) patients positive for steroid usage at 9 weeks after their last T injection. Fig. 1 chronologically contrasts the mean urine T/LH and T/E ratios. Inspection of Fig. 1 suggests that the urinary T/LH

ratio returns to baseline at a slower rate than the urinary T/E ratio does, thereby explaining the greater number of false-positive results for T/LH in this group. To prove this point, we regressed the mean T/E and T/LH ratios against their timepoints at weeks 17, 20, 24, 28, and 40 and fit this as a monoexponential decay curve. The regression line intersects the critical T/LH ratio of 30 at 7.9 weeks after the last TC injection (T/LH ratio = $90.2 e^{-0.14(\text{week})}$, $r^2 = 0.86$). However, the T/E ratio fitted to the exponential equation (T/E ratio = $12.3 e^{-0.1916(\text{week})}$, $r^2 = 0.80$) intersects the ratio of 6 at 3.7 weeks. Both models, therefore, demonstrate why more subjects test positive for a longer time when assessed with the T/LH ratio.

It is not uncommon for nonpower athletes (e.g., distance runners, swimmers, tennis players, soccer players) to utilize physiological doses of T (i.e., TC 100 mg/week) to counter the catabolic effects of stress and exercise on muscle. We measured urine T/E and urine T/LH in seven subjects who were administered TC at 100 mg/week. Monoexponential regression equations for the T/E and T/LH ratios to return to baseline values were based on the mean ratios measured in these subjects at weeks 17, 20, and 24 after cessation of TC injections. The urinary T/E ratio, when fitted as an exponential decay equation

Fig. 1. Urine T/LH ratios and T/E ratios in 19 subjects receiving TC, 250 or 500 mg/week.

(T/E ratio = $8.3 e^{-0.2072(\text{week})}$, $r^2 = 0.82$), intersects the ratio of 6 at 1.6 weeks, whereas the urinary T/LH ratio, fitted to the equation T/LH ratio = $48.9 e^{-0.2148(\text{week})}$ ($r^2 = 0.99$), intersects the ratio of 30 at 2.3 weeks. These data suggest that is debatable whether TC at 100 mg/week is actually a physiological replacement dose: Some athletes may test positive even at this small a dose of T.

In conclusion, we find that the urinary T/LH ratio is a more sensitive and specific test for a longer time for investigating AS use than is the urinary T/E ratio. Supporting this finding is the fact that, unlike the case for E, there are no commercially available FDA-approved LH products. This advantage alone makes the urinary T/LH ratio a considerably more practical screening test than the urinary T/E ratio.

This project was supported by a grant from the National Institute on Drug Abuse at the National Institutes of Health (RO1DA08347).

A Single Dose of the Potent Gonadotropin-Releasing Hormone Antagonist Acyline Suppresses Gonadotropins and Testosterone for 2 Weeks in Healthy Young Men

KAREN L. HERBST, ANDREA D. COVIELLO, STEPHANIE PAGE, JOHN K. AMORY, BRADLEY D. ANAWALT, AND WILLIAM J. BREMNER

Department of Medicine, Division of Endocrinology, Charles R. Drew University (K.L.H.), Los Angeles, California 90059; Center for Research in Reproduction and Contraception, Department of Medicine, University of Washington (A.D.C., S.P., J.K.A., B.D.A., W.J.B.), and Medical Service, Department of Veteran Affairs, Puget Sound Health Care System (B.D.A.), Seattle, Washington 98195

Acyline is a novel GnRH antagonist that reliably inhibits gonadotropins and testosterone (T) levels in men for 48 h after a single dose up to 75 $\mu\text{g/kg}$. In this study we examined gonadotropin and T levels in 28 healthy young men administered acyline as single doses of 150 or 300 $\mu\text{g/kg}$ or serial injections of 75 $\mu\text{g/kg}$. A single 300 $\mu\text{g/kg}$ dose of acyline suppressed gonadotropins and T to castrate levels for 15 d (baseline, 21.1 ± 3.1 ; nadir, 1.95 ± 0.4 nmol/liter; mean \pm SEM; $P < 0.05$). Serum acyline levels peaked 90 min after the injection of 300 $\mu\text{g/kg}$ acyline to a maximum concentration of 112.4 ± 18 ng/ml ($n = 7$; $t_{1/2} = 4.9$ d). Injections of 75 $\mu\text{g/kg}$ acyline every 2 d for five

doses suppressed gonadotropins for more than 20 d (nadir T, 1.06 ± 0.17 nmol/liter; $P < 0.05$ compared with baseline). Adverse events were mild and included erythema and pruritus at the injection site. Acyline, therefore, is one of the most potent peptide GnRH antagonists studied to date with minimal adverse events. A twice monthly injection of acyline could be used as a potent suppressor of the GnRH axis to advance the development of a hormonal male contraceptive or for treatment of hormonally dependent disease. (*J Clin Endocrinol Metab* 89: 5959–5965, 2004)

GnRH IS A hypothalamic decapeptide that is synthesized and released in a pulsatile manner from hypothalamic neurosecretory cells and regulates the synthesis and release of pituitary gonadotropins that, in turn, regulate steroidogenic and gametogenic functions of the gonads. GnRH plays a rate-limiting role in reproductive processes, and thousands of GnRH analogs have been generated because of their potential clinical utility. Most GnRH analogs are employed in the treatment of prostate cancer and for their utility in the disruption of LH surges for the regulation of ovulation induction in women undergoing *in vitro* fertilization (1–3). Other clinical uses for GnRH analogs include endometriosis and other gynecological diseases (4, 5), precocious puberty (6), and hormonal male contraception (7, 8). Both GnRH agonists and antagonists suppress gonadotropins and gonadal steroids, but the administration of GnRH agonists is accompanied by an initial gonadotropin and gonadal hormone surge known as a flare, delaying suppression by 7–14 d (2). GnRH antagonists do not cause flare, because they competitively block and inhibit GnRH-induced GnRH receptor gene expression, leading to immediate pituitary suppression.

Acyline is a GnRH antagonist sponsored by the NICHD that reliably maintained suppression of gonadotropins and testosterone (T) for 48 h with doses up to 75 $\mu\text{g/kg}$ by sc injection (9). We sought to determine whether larger or serial

doses of acyline would suppress gonadotropins and T for sufficiently long periods of time to allow a depot formation of acyline to be conveniently used for clinical applications such as a male hormonal contraception.

We administered acyline as single doses of 150 and 300 $\mu\text{g/kg}$ and as serial injections of 75 $\mu\text{g/kg}$ and monitored serum gonadotropin and T levels for a period of 30 d or until serum gonadotropins and T returned to baseline levels.

Subjects and Methods

Acyline

Acyline was originally synthesized by Jean Rivier at The Salk Institute (La Jolla, CA) (10) and is distributed by the NICHD. Acyline is prepared as a lyophilized powder (4.4 mg/vial) and is stored at -20°C . Acyline-lyophilized powder was suspended in bacteriostatic water to a final concentration of 2 mg/ml for injection into sc abdominal tissue. Serum levels of acyline were measured by RIA in a subset of subjects after the injection of 300 $\mu\text{g/kg}$ acyline, using a specific antiserum and a proprietary peptide with authentic peptide standard (Woods Assay, Inc., Portland, OR) as described previously (11). The sensitivity of the assay for acyline was 0.35 ng/ml.

Subjects

All study procedures involving human subjects were approved by the institutional review board at University of Washington and were performed at the University of Washington Clinical Research Center in accordance with institutional guidelines. Thirty-five men (age, 18–50 yr) were recruited by flyers posted on local college campus bulletin boards. All subjects were healthy, eugonadal men with normal medical histories and baseline physical examinations, including normal testicular size by Prader orchidometer and prostate size by digital rectal exam, serum chemistries, complete blood count, and gonadotropin and T levels. We excluded subjects who were current smokers, drank more than 7 oz

Abbreviations: ACY 150, 150 $\mu\text{g/kg}$ Acyline; T, testosterone.

JCEM is published monthly by The Endocrine Society (<http://www.endo-society.org>), the foremost professional society serving the endocrine community.

alcohol weekly, or had taken prescription medications or any sex steroid hormone within the last 6 months. Of these men, 34 were screened for study eligibility. Six men were excluded or withdrawn from the study after the screening process and before drug treatment: one man had low T levels, one man had abnormal hematology results at screening, one man had an elevated alanine aminotransferase test value, and two men had time constraints that prevented study participation. One subject was screened but did not begin the drug treatment phase, because recruitment for the study was complete.

Subjects were assigned to one of four groups ($n = 7$): group 1, single dose of 150 $\mu\text{g/kg}$ acyline on d 0 (ACY 150); group 2, single dose of 300 $\mu\text{g/kg}$ acyline on d 0 (ACY 300); group 3, 75 $\mu\text{g/kg}$ acyline injections on d 0, 4, and 8 and placebo on d 2 and 6 (ACY 75 \times 3); and group 4, 75 $\mu\text{g/kg}$ acyline injections on d 0, 2, 4, 6, and 8 (ACY 75 \times 5).

Acyline was administered by sc injection in the abdomen between 0700 and 1000 h. For ACY 150 and 300 groups, blood samples were obtained at 30, 60, 90, and 120 min; 3, 4, 6, 8, 12, and 24 h; and 2, 3, 4, 7, 9, 11, 13, 15, 17, 19, 21, 25, and 30 d after injection. For the serial injection groups ACY 75 \times 3 and 75 \times 5, blood samples were obtained on d 0, 2, 4, 6, 8, 10, 12, 14, 16, 18, 21, 25 and 30. All research subjects were monitored for 30 d with vital signs determined, and laboratory tests and physical exams performed.

Measurements

Hormones. FSH, LH, and T levels were measured by immunofluorometric assay (Delfia, Wallac Oy, Turku, Finland). Samples from a given individual were measured in a single assay. The sensitivities of the assay for FSH and LH were 0.016 and 0.019 IU/liter, respectively. For low, mid, and high pooled values of 0.054, 1.04, and 20.8 IU/liter FSH, the intraassay coefficients of variation were 12%, 1.9%, and 2.9%, and the interassay coefficients of variation were 18%, 6.1%, and 4.1%, respectively. For low, mid, and high pooled values of 0.056, 0.95, and 15.6 IU/liter LH, the intraassay coefficients of variation were 6.5%, 3.9%, and 5.4%, and the interassay coefficients of variation were 21%, 8%, and 6.6%, respectively. The assay sensitivity for T was 0.5 nmol/liter. For low, mid, and high pooled values of 3.8, 10.6, and 24.4 nmol/liter T, the intraassay coefficients of variation were 9.6%, 5.2%, and 6.1%, and the interassay coefficients of variation were 12%, 8.2%, and 6.7%, respectively. If serum T levels had not returned to baseline within 30 d after the injection of acyline, subjects were requested to return for additional blood sampling until serum T levels had normalized.

Serum laboratory tests. Screening and monitoring laboratory tests for complete blood count, electrolytes, glucose (chemistry 7), calcium, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, albumin, bilirubin, and total protein were performed at the University of Washington.

Statistics

FSH, LH, and T are expressed as the mean hormone level \pm SEM. For statistical analysis, all hormone data were log-transformed and then back-transformed for ease of presentation. Comparisons of data within groups and between groups were analyzed with ANOVA (SigmaStat, SPSS, Inc., Chicago, IL). Evidence for change from baseline within a group was further analyzed at each time point by paired t tests. The area under the curve was calculated using the trapezoid rule from time zero to the last measured level without smoothing or curve fitting (PK Solutions, Summit Research, Montrose, CO). The half-life ($t_{1/2}$) was calculated from 3 d to the last measured level. For all comparisons, an α of 0.05 was considered significant.

Results

Study population

The 28 subjects enrolled in this study were eugonadal and lean by body mass index (Table 1). There were no significant differences in baseline parameters between groups.

Acyline administration

Acyline was initially suspended in bacteriostatic water at a concentration of 8.8 mg/ml, which allowed acyline to be administered as a single, small volume injection at a concentration of 300 $\mu\text{g/kg}$ (2.4-ml injection for a 70-kg man). Nodule formation at the sites of acyline injection (lingering for as long as 30 d postinjection) suggested that the drug might be forming a gel in the fat tissue in a volume large enough to be palpable, similar to other GnRH antagonists (12). Suppression of gonadotropins and T was also inconsistent (data not shown). Acyline was therefore administered as a 2.0 mg/ml solution in water that does not lead to palpable nodule formation when injected into sc tissue (9), but did require multiple injections for a dose of 150 or 300 $\mu\text{g/kg}$. A 70-kg man administered 300 $\mu\text{g/kg}$ acyline at a concentration of 2.0 mg/ml would have an sc injection of 10.5 ml in four or five divided doses (2–3 ml/injection).

Single injections of acyline

Gonadotropins. Baseline levels of FSH and LH are shown in Table 1. Both FSH and LH decreased rapidly after a single dose of 150 or 300 $\mu\text{g/kg}$ acyline in all subjects (Fig. 1). In the ACY 150 group, FSH levels dropped significantly below baseline 8 h after injection, reaching a nadir at 3 d (1.06 ± 0.35 IU/liter), and remained significantly below baseline for 4 d after injection. LH levels decreased significantly below baseline by 1.5 h after injection, reached a nadir at 2 d (0.27 ± 0.05 IU/liter), and remained significantly below baseline for 3 d after injection.

In the ACY 300 group, FSH levels decreased significantly below baseline 1 h after injection and remained at these levels for 21 d, reaching a nadir on d 11 (0.26 ± 0.04 IU/liter). LH levels decreased significantly below baseline by 1.5 h after injection and reached a nadir at 2 d (0.17 ± 0.1 IU/liter), remaining significantly below baseline levels for 15 d. Gonadotropin levels tended to rebound above baseline by d 30 after the injection of acyline, but there was no significant difference between baseline and d 30 FSH or LH levels in the ACY 150 or ACY 300 groups.

T. Baseline levels of T for ACY 150 and ACY 300 are shown in Table 1. T rapidly decreased significantly below baseline

TABLE 1. Baseline parameters of subjects

| Group | ACY 150 | ACY 300 | ACY 75 \times 3 | ACY 75 \times 5 |
|--------------------------------------|----------------|----------------|-------------------|-------------------|
| n | 7 | 7 | 7 | 7 |
| Age (yr) | 26.6 \pm 2.7 | 31.9 \pm 3.8 | 30.9 \pm 2.1 | 23.0 \pm 1.8 |
| Body mass index (kg/m ²) | 26.1 \pm 1.7 | 24.5 \pm 0.7 | 25.6 \pm 1.1 | 26.2 \pm 1.6 |
| FSH (IU/liter) | 2.5 \pm 0.3 | 2.7 \pm 0.8 | 3.1 \pm 0.5 | 2.0 \pm 0.3 |
| LH (IU/liter) | 3.2 \pm 0.5 | 3.3 \pm 0.7 | 3.5 \pm 0.2 | 4.0 \pm 0.4 |
| T (nmol/liter) | 21.1 \pm 3.1 | 21.6 \pm 4.2 | 20.0 \pm 2.6 | 26.1 \pm 3.3 |

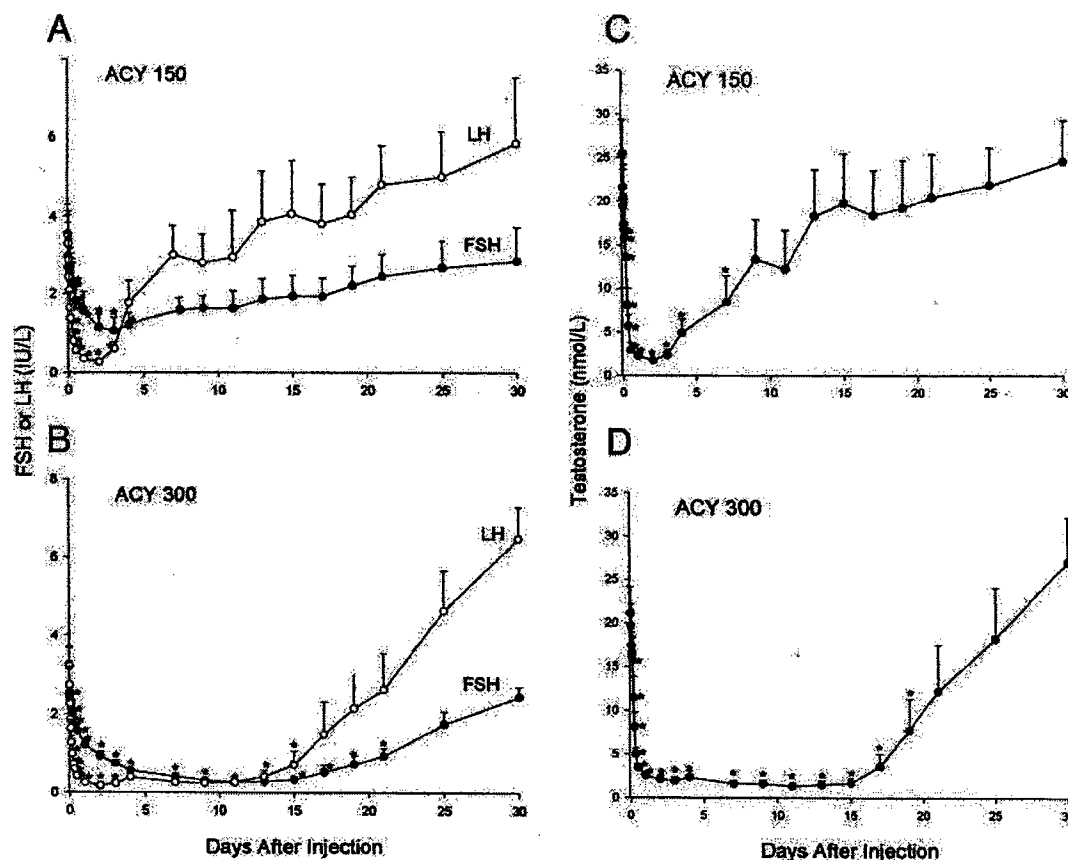

FIG. 1. Single injections of acyline rapidly suppress gonadotropins and T. Serum values of FSH (●) and LH (○) after 150 (A) and 300 (B) µg/kg acyline and serum values of T (●) after 150 (C) and 300 (D) µg/kg acyline are shown. Time is expressed as days after the first injection of acyline. Values (n = 7) are expressed as the mean ± SEM. *, $P < 0.05$ vs. baseline.

2 h after injection in all subjects after single acyline doses and decreased below castrate levels (5 nmol/liter) by 12 h after injection (Fig. 1). T levels reached a nadir in the ACY 150 group 2 d after injection (1.75 ± 0.28 nmol/liter) and began to rise but remained significantly below baseline through d 7 after injection. One subject's T level remained below baseline levels until d 37.

T levels reached a nadir on d 2 after injection in the ACY 300 group (1.95 ± 0.38 nmol/liter) and remained at approximately this same level through d 15. T levels began increasing on d 17 after injection, remaining significantly below baseline levels until d 19 after injection, but were not significantly different from baseline levels on d 21. One subject's T level remained below baseline levels until d 35. On the average, there was no significant difference between baseline and d 30 T levels in either group.

Multiple injections of acyline

Gonadotropins. In the ACY 75X3 group, FSH and LH levels decreased significantly below baseline on d 2 (Fig. 2, A and B). Gonadotropin levels increased before the next injection on d 4, but remained significantly below baseline, then decreased on d 6, reaching steady suppressed levels on d 10–18 after the third injection. The nadir level of FSH on d 18 was 0.39 ± 0.08 IU/liter, and the nadir level for LH was 0.16 ± 0.04 IU/liter on d 10. LH and FSH levels remained signifi-

cantly below baseline through d 21 and 25, respectively, but the levels normalized and were not significantly different from baseline levels by d 30.

In the ACY 75X5 group, LH and FSH decreased significantly below baseline by d 2 (Fig. 2, C and D). LH levels remained significantly suppressed below baseline from d 2–16, with a nadir level on d 10 (0.07 ± 0.01 IU/liter). FSH levels gradually decreased to a nadir on d 12 (0.1 ± 0.01 IU/liter) and remained significantly below baseline on d 2–25.

T. In the ACY 75X3 group, T decreased significantly below baseline levels after the first acyline injection (Fig. 3A), with small rebound increases before the second and third injections. T levels reached a nadir on d 10 after the third injection (1.29 ± 0.22 nmol/liter), remained significantly below baseline levels from d 2–21, and returned to baseline by d 30. Two subjects' T levels remained below baseline on d 30, but returned to baseline levels by d 33 and 47, respectively.

In the ACY 75X5 group, T levels decreased rapidly and significantly below baseline, reaching a nadir on d 17 (1.06 ± 0.17 nmol/liter) after the first injection and remained significantly suppressed through d 25, returning to baseline levels by d 30. Four subjects' T levels remained significantly below baseline levels on d 30, returning to baseline levels on d 36, 37, 45, and 47, respectively.

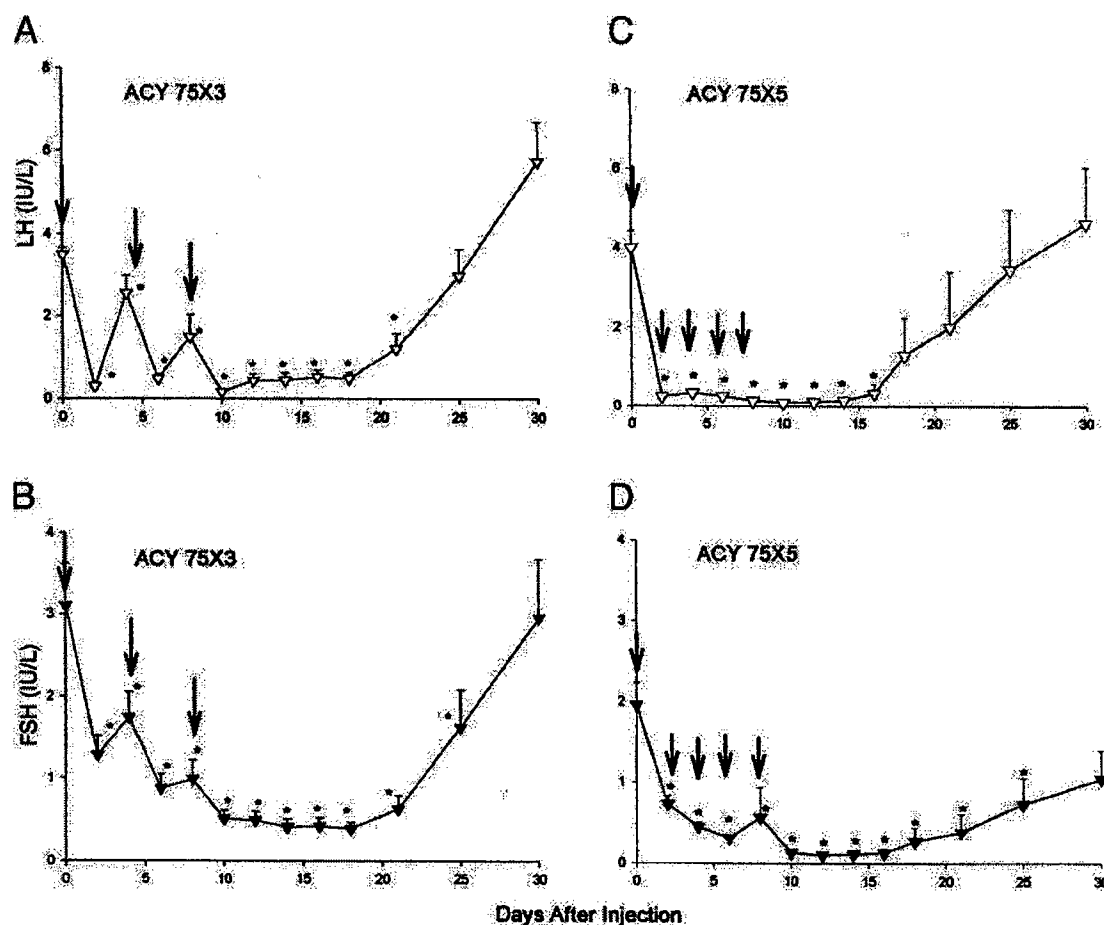

FIG. 2. Multiple injections of 75 µg/kg acyline can maintain suppression of gonadotropins for more than 20 d. Serum values of LH (A; Δ) and FSH (B; \blacktriangle) after three injections of 75 µg/kg acyline spaced 4 d apart (arrows) and LH (C) and FSH (D) levels after five injections of 75 µg/kg acyline spaced 2 d apart (arrows) are shown. Time is expressed as days after the first injection of acyline. Values ($n = 7$) are expressed as the mean \pm SEM. *, $P < 0.05$ vs. baseline.

Acyline pharmacokinetics

Serum acyline levels were measured in all seven subjects in the ACY 300 group (Fig. 4). Acyline reached a maximum concentration of 112.4 ± 6.9 ng/ml 90 min after injection and remained significantly elevated above background through d 30. Blood levels of acyline dropped by 50% at 4.9 d.

Adverse events and safety

Skin reactions were the most common side-effect noted after sc acyline injections. A mild pink blush occurred at the site of injection in 22 of 28 subjects (78.5%), lasting up to 120 min. The blush occurred in 94% of injections in subjects who experienced it. Pruritus at the site of injection occurred in 75% of subjects, with an average score of 2.3 ± 0.1 arbitrary units of 5: 0 = no itch, 1 = barely noticeable, 2 = mild, 3 = moderate, 4 = severe, and five = the worst itch ever experienced. The pruritus persisted for approximately 40 min on the average. Nodules or deep induration were noted in three individuals, one in each of the groups receiving single acyline doses (although multiple injections), and persisted at 2 and 11 d; in one subject receiving serial injections, they persisted for 2 d. Bruising at the site of injection was also noted in 12

individuals (42.9%), although not at all injection sites. During the hypogonadal period (T, <5 nmol/liter), 10 subjects experienced decreased libido or fatigue (35.7%), and two experienced hot flashes or significant changes in mood/irritability (7.1%). One subject experienced myalgia without signs of infection, including fever. There were no significant changes in any chemistry parameter during the study, including aspartate aminotransferase and alanine aminotransferase. The hematocrit decreased slightly in all 28 subjects from an average baseline value of $42.5 \pm 0.46\%$ to $41.1 \pm 0.49\%$ ($P < 0.01$), remaining in the normal range (38–50%). The white blood cell and platelet counts were unaffected by acyline administration.

Discussion

GnRH antagonists competitively block and inhibit GnRH-induced GnRH receptor gene expression, leading to immediate pituitary suppression (13) without the surge in gonadotropins and T seen after GnRH agonist administration (14). The GnRH antagonist, acyline, was developed to have greater potency and less histamine-mediated skin irritation than previous antagonists (10). A single injection of 300

FIG. 3. Multiple injections of 75 $\mu\text{g/kg}$ acyline can maintain suppression of T for more than 20 d. Serum values of T (\diamond) after three injections of 75 $\mu\text{g/kg}$ acyline spaced 4 d apart (A, arrows) and five injections of 75 $\mu\text{g/kg}$ acyline spaced 2 d apart (B, arrows). Time is expressed as days after the first injection of acyline. Values ($n = 7$) are expressed as the mean \pm SEM. *, $P < 0.05$ vs. baseline.

$\mu\text{g/kg}$ acyline in this study rapidly and significantly suppressed gonadotropins and T to castrate levels (T, < 5 nmol/liter) for 15 d. Five injections of 75 $\mu\text{g/kg}$ acyline spaced 2 d apart also immediately suppressed gonadotropins and T and maintained T within the castrate range for up to 21 d. Five injections of 75 $\mu\text{g/kg}$ acyline might have suppressed the hypothalamic-pituitary-gonadal axis longer than the single 300 $\mu\text{g/kg}$ dose, because the cumulative dosage administered was greater at 375 $\mu\text{g/kg}$. Alternatively, because 75 $\mu\text{g/kg}$ is known to rapidly and effectively suppress gonadotropins and T for up to 48 h (9), serial injections of acyline every 2 d over an 8-d period might simply maintain that 48-h suppression. However, if the latter were true, then gonadotropins would be expected to begin returning to baseline approximately 48 h after the last injection. Instead, FSH and LH were still suppressed 8 d after the last of five injections of 75 $\mu\text{g/kg}$ acyline.

FIG. 4. Serum levels of acyline (nanograms per milliliter) remained significantly elevated for 30 d after sc injection of 300 $\mu\text{g/kg}$ acyline in seven healthy young men. Values are the mean \pm SEM after subtraction of 1 ng/ml background levels. *, $P < 0.05$ vs. baseline.

Cetrorelix is a GnRH antagonist that has similar potency to acyline (9, 15). Data examining the effect of cetrorelix on pituitary GnRH receptor expression and localization might help explain why serial injections of 75 $\mu\text{g/kg}$ acyline induce longer suppression of gonadotropins than a single 300 $\mu\text{g/kg}$ injection (15–18). GnRH receptors were significantly down-regulated for at least 72 h in rat pituitaries, accompanied by suppression of serum LH and T, after a single injection of 100 μg cetrorelix (16). The lowest receptor level was found 6 h after the injection of cetrorelix, but a marked recovery in receptor number was observed at 48 h. A major decrease in the expression of mRNA for pituitary LH-releasing hormone receptors was also found after chronic treatment with cetrorelix (17). This suppression is not believed to be a direct effect on gene expression of the GnRH receptor, but due to the fact that GnRH antagonists prevent up-regulation of receptor mRNA expression induced by GnRH (18). These data suggest that the prolonged suppression of gonadotropins and T by serial injections of 75 $\mu\text{g/kg}$ acyline is not only a reflection of the concentration of the antagonist at the level of the receptor, but that administration every 48 h might have prevented the up-regulation of GnRH receptor mRNA expression longer than the single dose of 300 $\mu\text{g/kg}$.

The question then becomes how is acyline best administered. Subjects and patients would probably prefer a single dose of sc acyline twice a month to serial injections. However, serial injections maintained suppression of gonadotropin and T levels longer than either single dose, as demonstrated by the four subjects whose T levels remained significantly below baseline more than 30 d after the start of the five injections. A minimal dose for a twice monthly injection might be 225 $\mu\text{g/kg}$, because gonadotropins and T were suppressed in the hypogonadal range for 14 d after three injections of 75 $\mu\text{g/kg}$ acyline. Alternatively, a higher dose injection than 300 $\mu\text{g/kg}$ might maintain acyline concentrations in the pituitary at a sufficiently high level to prevent up-regulation of GnRH receptor mRNA. The GnRH antagonist, abarelix, is administered as a 100-mg monthly injection to maintain suppression of serum gonadotropins and T (2). The amount of acyline administered to a 70-kg man in this

study as a 300 $\mu\text{g/kg}$ injection was 21 mg, approximately 5 times less than the dose of abarelix. It is therefore possible that a single higher dose of acyline might suppress gonadotropins and T for a month. The only drawback is the volume of acyline that would need to be administered (10.5 ml). A depot formulation of acyline is currently under development by the NICHD.

Adverse side-effects with acyline injection were again minimal, similar to our previous study (9), and included a blush at the injection site and mild pruritus. In this study, however, there was more bruising at the site of injection. There was no pattern to the bruising; it did not occur more commonly for specific individual subjects and was not associated more often with individual nurses who administered the injections. We believe that the bruising probably reflects differences in the manner the injection was administered, rather than being a result of the acyline itself. Three sc nodules at the site of injection were noted in this study: two lasting for 2 d, and one lasting 11 d. Because nodule formation did not occur with every injection in these individuals, these nodules probably represent a tissue reaction to the injection, rather than a reaction to acyline itself.

Other adverse events that occurred during this study in the hypogonadal period were expected as a result of declining T levels. These included hot flashes, decreased libido, fatigue, and irritability, consistent with symptoms of male hypogonadism (19, 20). Because T is known to increase the production of erythropoietin (21, 22), and castration decreases hemoglobin levels (23), our data demonstrating a small, but significant, decrease in hematocrit within the normal range was predictable.

The amount of time for acyline levels in serum to decrease by half ($t_{1/2}$) in this study was 4.9 d, greater in length than the 28.3 h previously found (9). This calculated $t_{1/2}$ for acyline in serum does not fit the classical definition of a true $t_{1/2}$, because it reflects not only the time required for half the total amount of acyline to be cleared from the serum, but also the rate of entry of acyline into serum from the presumed sc depot. Nevertheless, this calculated $t_{1/2}$ allows us to compare data from different studies. The difference found in the $t_{1/2}$ values between the two studies probably reflects the increased number of subjects tested for acyline levels in this study ($n = 7$) vs. the former study ($n = 4$), the similarity in suppression of gonadotropins in the current study (only two of four subjects had suppression of gonadotropins and T for 7 d in the previous study), and the higher dosage of acyline administered in the current study. The long calculated $t_{1/2}$ of acyline might also represent the ability of acyline to bind to serum proteins, as previously discussed (9), or a prolonged time of entry from the sc tissue into the serum compartment secondary to increased volume of injections.

Conclusion

Acyline is a likely candidate for use as a potent, long-lasting GnRH antagonist in the development of an effective male hormonal contraceptive regimen or for the treatment of sex steroid hormone-dependent syndromes, such as advanced severe endometriosis and prostate cancer. It is safe and potentially can be administered as a single dose, twice

a month. Because exogenous long-acting T formulations also inhibit circulating gonadotropins levels and spermatogenesis, a combination of long-acting acyline plus T might make a male hormonal contraceptive regimen a safe, effective, and practical option.

Ferrando, Arny A., Melinda Sheffield-Moore, Catherine W. Yeckel, Charles Gilkison, Jie Jiang, Alison Achacosa, Steven A. Lieberman, Kevin Tipton, Robert R. Wolfe, and Randall J. Urban. Testosterone administration to older men improves muscle function: molecular and physiological mechanisms. *Am J Physiol Endocrinol Metab* 282: E601–E607, 2002. First published November 13; 10.1152/ajpendo.00362.2001.—We investigated the effects of 6 mo of near-physiological testosterone administration to older men on skeletal muscle function and muscle protein metabolism. Twelve older men (≥ 60 yr) with serum total testosterone concentrations < 17 nmol/l (480 ng/dl) were randomly assigned in double-blind manner to receive either placebo ($n = 5$) or testosterone enanthate (TE; $n = 7$) injections. Weekly intramuscular injections were given for the 1st mo to establish increased blood testosterone concentrations at 1 mo and then changed to biweekly injections until the 6-mo time point. TE doses were adjusted to maintain nadir serum testosterone concentrations between 17 and 28 nmol/l. Lean body mass (LBM), muscle volume, prostate size, and urinary flow were measured at baseline and at 6 mo. Protein expression of androgen receptor (AR) and insulin-like growth factor I, along with muscle strength and muscle protein metabolism, were measured at baseline and at 1 and 6 mo of treatment. Hematological parameters were followed monthly throughout the study. Older men receiving testosterone increased total and leg LBM, muscle volume, and leg and arm muscle strength after 6 mo. LBM accretion resulted from an increase in muscle protein net balance, due to a decrease in muscle protein breakdown. TE treatment increased expression of AR protein at 1 mo, but expression returned to pre-TE treatment levels by 6 mo. IGF-I protein expression increased at 1 mo and remained increased throughout TE administration. We conclude that physiological and near-physiological increases of testosterone in older men will increase muscle protein anabolism and muscle strength.

aging; muscle strength; lean body mass; insulin-like growth factor I

MOST AGING MEN SHOW A REDUCTION in circulating serum testosterone concentrations (16, 22). This reduction in serum testosterone concentration is a core physiological event in what is termed andropause. Andropause

can be clinically characterized by decreased potency and libido, increased fatigability, and decreased muscle strength (13, 24). A significant decrease in serum total testosterone occurs as early as ages 50–59 (16). This decrease in testosterone production is associated with the loss of lean body mass (LBM) and muscle strength. When men are made hypogonadal with a gonadotropin-releasing hormone analog (14), LBM and muscle strength are lost. Once weakened, older individuals are prone to falls that prevent an independent living status and diminish the quality of life. As the population of older Americans grows, the need to develop therapies to counteract the aging-induced loss in skeletal muscle mass and function becomes critically important.

Previously we demonstrated that testosterone administration primes skeletal muscle for growth by increasing net protein synthesis in the fasted state (10, 18). The logical extrapolation of a continued increase in net protein synthesis is an increase in lean body mass and strength. Bhasin et al. (2) demonstrated that supraphysiological doses of testosterone can induce increases in muscle size and strength in younger men without concomitant exercise. This relationship holds true in relatively hypogonadal populations, where the increase of circulating testosterone increases muscle protein synthesis (23), LBM (3, 20), and muscle strength (3, 23). In an earlier study (23), we demonstrated that 1 mo of testosterone administration increased muscle anabolism and strength in six older men. We also demonstrated that the increase in muscle anabolism was associated with an increase in the expression of intramuscular mRNA for insulin-like growth factor I (IGF-I) (23). Because IGF-I has also been demonstrated to be a potent anabolic hormone (11), the relationship between testosterone administration and IGF-I levels was investigated in the present study.

Previous studies of testosterone administration in older men used a standard clinical dosing paradigm (3, 15, 21). Although this dosing is clinically feasible and

convenient, it does not account for individual response to hormone administration. We have previously noted that a given dosage of testosterone administration results in widely varied blood concentrations (23). Although group means often reveal significant increases in testosterone, individual variation may mask a consistency in outcomes. For example, Bhasin et al. (3) and Tenover (21) each used a standard clinical replacement dose in elderly men for up to 3 mo. However, Bhasin et al. demonstrated an increase in muscle strength, whereas Tenover did not. Individual response can be resolved in part by using supraphysiological doses (2); however, these doses may be associated with the potential for increased side effects such as altered lipid profiles (12) or hemodynamic profiles (15). In the present study, we endeavored to adjust individual testosterone concentrations to remain within the mid- to high physiological range. We reasoned that remaining within or near physiological testosterone concentrations would diminish potential side effects while allowing the investigation of testosterone's anabolic effects. We hypothesized that increases in testosterone within or near the physiological range would also stimulate muscle anabolism and increase muscle strength in older men much like previous studies where supplementation resulted in supraphysiological concentrations (2, 15). To accomplish this, we carefully adjusted individual nadir hormone concentrations to remain within the physiological range throughout the 6-mo study. This dosing paradigm permits the investigation of the efficacy of long-term testosterone administration at or near physiological concentrations in older men.

METHODS

Subjects. Twelve healthy, older male subjects were randomly assigned in double-blind fashion to receive either testosterone enanthate (TE) or placebo for 6 mo. Seven subjects [68 ± 3 (SE) yr; 91 ± 5 kg] were randomized to receive TE, whereas five subjects (67 ± 3 yr; 99 ± 7 kg) received a placebo consisting of sesame seed oil. The study was approved by the Institutional Review Board at The University of Texas Medical Branch (UTMB). Informed consent was obtained after the study was explained to each individual. Subjects were selected on the basis of the following inclusion criteria: 1) prostate-specific antigen (PSA) ≤ 4.0 $\mu\text{g/l}$ (6), 2) serum total testosterone ≤ 17 nmol/l (480 ng/dl), 3) serum low-density lipoprotein (LDL) ≤ 200 ng/dl (7), 4) completion of a Bruce treadmill exercise test without significant findings of cardiovascular disease, and 5) no medical illnesses causing disability. The serum testosterone cutoff was chosen because it has been shown that 85% of healthy older men (age 60–98 yr) have serum testosterone concentrations < 17 nmol/l but still in the low-normal range of > 10 nmol/l (1). Exclusion criteria included a history of prostate cancer and severe coronary artery disease (due to the possible hypertrophic and atherogenic effects of testosterone), knee replacement (for reasons of strength determination), or use of a blood anticoagulant, e.g., Coumadin (for fear of excessive bleeding during biopsy and catheterization procedures). Because we wanted to determine the outcomes of testosterone without the confounding effects of exercise (2), we excluded subjects engaged in regular training (defined as 30 min of aerobic or resistance

training activity ≥ 2 days/wk). These exclusion/inclusion criteria were similar to those of previously published studies by our group and others (21, 23).

Experimental protocol. The studies were performed at the General Clinical Research Center (GCRC) at UTMB. Subjects were studied at baseline, after 1 mo, and after 6 mo of treatment. Each GCRC admission consisted of ~ 3 days. On day 1, subjects were admitted in the afternoon and underwent Cybex II isokinetic dynamometer testing for muscular endurance. Subjects followed a standardized protocol that included 15 min of pretest stretching. Muscular endurance was defined as the total work performed for 20 repetitions at $240^\circ/\text{s}$. On the morning of day 2, subjects were weighed in hospital gowns, resting (recumbent) blood pressure was taken, and blood was drawn from the fasted subjects for hematological measures. Subjects were then taken for magnetic resonance imaging (MRI) of the lower body. Leg muscle volume was determined by analysis of images collected by MRI (GE Signa 1.5-Tesla whole body imager; General Electric, Milwaukee, WI) as previously described (9). Image data files generated at the MRI facility were analyzed for appendicular total and muscle volumes using NIH Image software (NIH Image public domain analysis package). Muscle volume (cm^3) was computed as the addition of individual slice areas multiplied by the slice thickness (10 mm). After breakfast, subjects were taken to the UTMB Field House for one-repetition maximum (1RM) determinations for bicep curl, tricep extension, leg extension, and leg curl on specific equipment (Cybex) designed for each movement. Subjects were initially familiarized on the equipment after screening and selection. For 1RM testing, subjects first warmed up on a stationary bike set at 30 W for 10 min. The determination of 1RM was accomplished by increasing the load on each machine until successful completion of the movement was no longer possible. The heaviest load lifted was considered the 1RM. At approximately noon, subjects received dual-energy X-ray absorptiometry (DEXA) to determine LBM and fat mass. Body mass components were determined with regional analysis software as previously described (8). Finally, subjects were referred to the Department of Urology at UTMB for prostate ultrasound and urine flow measurements. Prostate volume was measured by transrectal ultrasound, and urinary flow rate measures were made using a Life-Tech uroflowmeter (Life Tech, Houston, TX).

On day 3, subjects received a stable isotope infusion to determine skeletal muscle protein metabolism. Muscle protein net balance and fractional synthesis rate (FSR) of skeletal muscle were determined by infusion of the stable isotope [^3H]ketoisocaproic acid, arteriovenous sampling, and muscle biopsies as previously described (10). Briefly, skeletal muscle FSR was calculated from the determination of the rate of tracer incorporation into the protein and the enrichment of the intracellular pool as the precursor

$$\text{FSR} = [(E_{p2} - E_{p1}) / (E_M \cdot t)] \cdot 60 \cdot 100$$

where E_{p1} and E_{p2} are the enrichments of the protein-bound [^3H]leucine (from transamination of [^3H]ketoisocaproic acid) from the biopsies at 2 and 5 h of isotope infusion; E_M represents the average intracellular [^3H]leucine enrichment over the time of incorporation; and t is the time in minutes. The factors 60 and 100 are required to express FSR in percent per hour. Each biopsy was divided to be used for both Western blot and isotopic enrichment analyses.

After the isotope infusion study on day 3, subjects were given injections and discharged. Subjects returned every week for fasted blood draw and injections for the first 4 wk and then every 2 wk for the remainder of the study. Serum

total testosterone concentrations were measured on each occasion and adjusted to between 17 and 28 nmol/l (500 and 800 ng/dl; based on the concentration for the visit before each injection) to approximate concentrations found in young men. The aforementioned measurements were made at baseline and at 1 and 6 mo. However, at 1 mo, the MRI, DEXA, and urology measures were omitted. We designed the TE dosing paradigm for weekly injections for the 1st mo so that we could adjust TE doses and establish increased testosterone concentrations by the first measurements that were done at 1 mo. This paradigm was reproduced from our initial study (23). A biweekly injection paradigm would not have allowed TE dose adjustment before the assessments at 1 mo.

Clinical measures. Measurement of clinical parameters (see Table 2) such as testosterone (DPC, Los Angeles, CA), estradiol (DPC), blood lipids (Vitros 250 Chemistry System, Johnson & Johnson, Arlington, TX), PSA, liver function tests (Vitros 250), and hematocrit (Couter Onyx, Beckman Coulter, Brea, CA) were done on a monthly basis by a UTMB clinical laboratory. Subjects were also monitored monthly for breast tenderness and the presence of gynecomastia by history and physical examination. Serum testosterone concentrations were determined by the clinical laboratory, so that adjustments in TE doses could be made on the basis of the previous serum testosterone concentration.

Western blot analysis. Protein was isolated from muscle biopsy samples by slicing frozen muscle in very small pieces with a clean razor blade and thawing the tissue in lysis buffer (150 mM NaCl, 10 mM Tris, 1% Triton X-100, 1% Na deoxycholate, 0.1% SDS, 5 mM EDTA) containing protease inhibitors (1 mM phenylmethylsulfonyl fluoride, 1 mM benzamide, 10 μ g/ml aprotinin, 50 μ g/ml leupeptin, 1 μ g/ml pepstatin A) at a concentration of 3 ml of ice cold lysis buffer per gram of tissue. The tissue was homogenized with a Dounce homogenizer (4°C) and centrifuged at 15,000 *g* for 20 min, and the supernatant was removed and centrifuged again to result in total cell lysate. The androgen receptor (AR) antibody (Santa Cruz Biotechnology, Santa Cruz, CA) was incubated with 80 mg of cell lysate run on standard SDS-PAGE gel with a working solution concentration range of 1:15–20. The IGF-I antibody (Santa Cruz Biotechnology) was incubated with 40 mg of cell lysate run on standard SDS-PAGE gel with a working solution concentration of 1:100. The actin “housekeeping” antibody (Sigma) was used with a working solution concentration range of 1:100–200. This anti-actin antibody is a broad-based antibody that recognizes an epitope located on the NH₂-terminal region of actin and demonstrates a broad reactivity among multiple actin isoforms in various species. The housekeeping antibody was used to correct the results for protein loading of the gel. Western analysis allows the direct measurement of protein expression in the muscle biopsy samples.

Statistical analysis. Comparison of 1- and 6-mo measures to baseline values was accomplished by 2-way repeated-measures ANOVA with Dunnett's multiple comparison test. Comparison of clinical outcome values over the 6-mo study period was accomplished by ANOVA with Dunnett's multiple comparison test. Where 1-mo measures were omitted, a paired *t*-test was used to statistically compare 6-mo and baseline values. Statistical significance was $P \leq 0.05$. Data are presented as means \pm SE.

RESULTS

Clinical outcomes. Figure 1 shows the mean testosterone profiles of each group at 2-wk intervals over the 6-mo study period. Table 1 shows the individual tes-

Fig. 1. Serum testosterone profiles throughout treatment. Values are means \pm SE. Testosterone treatment group values were significantly higher at all time points after baseline. Arrows indicate study time points.

tosterone concentrations for each of the seven subjects who received TE and the dose adjustment made for each individual. None were clinically hypogonadal at the beginning of this study. TE injections were adjusted by an independent clinician to maintain levels within the normal range (17–28 nmol/l). As can be seen in Table 1, the serum testosterone concentrations and the doses of TE administered were variable from individual to individual. Following such a paradigm, especially with the use of intramuscular injections, the older men were exposed to serum testosterone concentrations at various times during the 6-mo study that were above the physiological range. Therefore, this study assesses a mix between physiological and near-physiological administration. However, serum testosterone concentrations were greater in the treatment group at all time points after baseline ($P < 0.05$). Serum testosterone did not change in the placebo group. Table 2 delineates subject characteristics and laboratory values over the 6-mo study period. Treatment subjects remained normotensive, and liver function tests, blood lipid profiles, and PSA were unchanged. Estradiol increased upon treatment and, for the most part, remained elevated throughout the 6-mo period without causing breast tenderness or gynecomastia by report or examination. Hematocrit was elevated after 4 mo of TE and remained elevated until the end of the study.

Prostate volume was not significantly increased with TE administration. Prostate volume in the treatment group was 44 ± 15 ml at baseline, whereas the placebo group was 41 ± 8 ml. Six-month values were 47 ± 13 and 35 ± 7 ml, respectively, for the treatment and placebo groups. Urinary flow rate also did not change over time or as a result of treatment. Baseline flow rate was 8.3 ± 1.5 and 8.9 ± 1.3 ml/s, whereas 6-mo values were 7.5 ± 1.4 and 8.7 ± 1.6 ml/s for the treatment and placebo groups, respectively.

Western blot analysis. TE administration significantly increased skeletal muscle AR protein expression at 1 mo ($P < 0.05$), but AR returned to baseline levels at 6 mo. Figure 2 shows a representative autoradio-

Nos. are testosterone concentrations in nmol/l; nos. in parentheses are doses of testosterone enanthate (TE) administered (mg) at that visit. S, subject. Testosterone dose adjustments were made on the basis of the preceding testosterone concentrations; i.e., an adjustment at 8 wk was based on the 6-wk testosterone concentration.

gram of a Western blot for skeletal muscle AR from a subject receiving testosterone and a graph of the densitometry data from the treatment group. There was no correlation between the serum testosterone concentration at 1 mo and the change of AR expression from baseline to 1 mo for individuals. IGF-I protein expression in skeletal muscle increased at 1 mo and remained elevated at 6 mo ($P < 0.05$; Fig. 3). AR and IGF-I protein expression did not change in the placebo group (data not shown).

Physiological outcomes. The net balance of muscle protein was less negative in the fasted state in the treatment group throughout TE administration (Fig. 4; $P < 0.05$), but still less than zero. In other words,

treatment subjects were less catabolic when fasting than those in the placebo group. The more favorable net balance was due to a decrease in fasting protein breakdown, as fractional synthetic rate of muscle protein remained constant throughout (0.071 ± 0.02 to 0.084 ± 0.013 to $0.062 \pm 0.016\%/h$ at baseline and 1 and 6 mo, respectively).

The resultant improvement in net protein balance led to an increase in LBM. Table 3 outlines the changes in LBM and muscle strength over the 6-mo study period. The treatment group demonstrated increases in total and leg LBM, whereas the percentage of total body fat diminished. Leg muscle volume by MRI was also increased significantly after 6 mo of TE adminis-

Fig. 2. Androgen receptor (AR) protein expression in skeletal muscle during 6 mo of testosterone administration in older men. *Top*: representative Western blot from one of the 7 subjects assessed for protein expression of AR by use of standard Western analysis. Actin was used as an internal control for protein loading. *Bottom*: means \pm SE from the 7 subjects that received testosterone. Five subjects who received placebo demonstrated no change throughout the study in AR expression (data not shown). Data are expressed as arbitrary units calculated as the ratio of the band densities of AR over the band densities of actin. *Statistical significance was determined by ANOVA, $P \leq 0.05$.

tration. All 1RM strength scores increased in the treatment group after 6 mo of TE. Muscular endurance, as tested by an isokinetic dynamometer, did not increase at 1 or 6 mo.

DISCUSSION

This study demonstrates that testosterone increases within or near the physiological range can produce increases in muscle anabolism, LBM, and muscle strength similar to supraphysiological administration. We monitored serum testosterone concentrations and adjusted the dose of TE to maintain testosterone concentrations in older men in ranges comparable with those of younger men. During the 6 mo of TE administration, some subjects experienced testosterone concentrations that exceeded the physiological; however,

Fig. 3. Insulin-like growth factor I (IGF-I) protein expression in skeletal muscle during 6 mo of testosterone administration in older men. *Top*: representative Western blot from one of 7 subjects assessed for expression of IGF-I by use of standard Western analysis. *Bottom*: mean data from the 7 subjects receiving testosterone administration. Five subjects who received placebo demonstrated no change throughout the study in IGF-I expression (data not shown). Data were derived as described in Fig. 2.

Fig. 4. Fasting net phenylalanine balance across the leg. Phenylalanine net balance describes the net balance between muscle protein synthesis and breakdown. *Significantly less negative than the placebo group and baseline testosterone, by ANOVA, $P < 0.05$.

testosterone concentrations were consistently maintained above baseline values. The older men in this study demonstrated an increase in LBM that was comparable to that achieved with a standard replacement regimen that resulted in higher testosterone concentrations (5). We also found that, similar to younger men (2), testosterone will increase muscle anabolism and strength in older men. The strength increases of the older men in this study were greater than those demonstrated with standard replacement paradigms (15, 21) or with testosterone patch administration over

36 mo (20). Our data suggest that a standard paradigm of testosterone administration that does not include individual dose adjustment may not always achieve desired outcomes if the subjects have not received adequate testosterone to stimulate metabolic changes in muscle. Because we studied only a small number of subjects, we cannot draw any conclusions regarding the risk-to-benefit ratio of testosterone administration in older men. However, we found no significant side effects in our small group other than an increase in hematocrit. Our data indicate that testosterone can improve muscle strength in older men when careful dosing ensures sustained blood testosterone increases. Our first study demonstrated that short-term administration with standard replacement dosages resulted in LBM and strength increases (23). The present study indicates that these LBM and strength increases can be maintained over 6 mo with careful dose adjustments that ensure primarily physiological testosterone levels. This study also demonstrates that the muscle's response to testosterone changes over the 6-mo period of administration, indicating that alternative paradigms of testosterone administration (i.e., cyclic administration) can be of physiological benefit.

Testosterone administration resulted in some noteworthy effects on AR and IGF-I expression in skeletal muscle. AR protein expression was increased after 1 mo of TE but had returned to pretreatment levels by 6 mo. Physiologically, it is logical that androgen would enhance its own receptor expression as it stimulates muscle metabolism. We previously noted an upregulation of AR expression with oxandrolone administration (18) in young males, which also occurred concomitantly with an increase in muscle protein synthesis. The return of AR expression to pretreatment values after 6 mo of continuous androgen administration indicates a steady-state adaptation to the treatment paradigm. There is also the possibility that the AR response is nothing more than a response to the dosing paradigm. At 1 mo, older subjects were receiving TE weekly rather than every 2 wk, and their mean serum testosterone concentrations were more in the supraphysiological range than they were at 6 mo. However, this relationship is weakened by the fact that individual testosterone concentrations at 1 mo did not correlate with the change in AR expression from baseline to 1 mo. This pattern of AR expression raises the possibility that cycling of testosterone administration could produce effects on skeletal muscle analogous to continuous administration. Such a paradigm would be beneficial by administering significantly less testosterone for similar anabolic outcomes, thus minimizing the possibility of side effects.

IGF-I accompanies increases in muscle mass and strength (17). In frail elderly, progressive resistance training that increases muscle mass and strength also increases intramuscular IGF-I concentrations (19). Clinically, we previously demonstrated that older men given testosterone for 1 mo increased IGF-I transcripts in muscle while decreasing the inhibitory IGF-binding protein (23). The present study agrees with our previ-

ous work in that IGF-I protein expression increased at 1 mo and further demonstrates that this increase was maintained throughout the 6 mo of testosterone administration. This confirms that the increase in IGF-I mRNA noted in our earlier study (23) translates into an actual increase of IGF-I protein. A corollary to these studies found that young men who were made hypogonadal for 10 wk by Lupron showed a decrease in muscle strength and a decrease in intramuscular IGF-I mRNA concentration (14). Taken together, these data indicate a mechanistic importance of IGF-I on muscle anabolism.

Although the intracellular mechanism stimulating muscle protein anabolism requires further clarification, it is clear that testosterone improves net protein balance of skeletal muscle. This effect is pronounced in the fasted state as net protein balance becomes less negative. We have previously demonstrated (10, 18) that one of the primary effects of testosterone (during fasting) is the efficient reutilization of intracellular amino acids (derived from protein breakdown) for protein synthesis. However, the present study demonstrates that, even if breakdown is decreased, ample amino acid precursors are present to support the initial rate of protein synthesis. Thus testosterone administration may ameliorate the loss of skeletal muscle nitrogen during fasting in this older population by preventing the loss of intracellular amino acids. Not only is the appearance of amino acids from protein breakdown reduced, but those that are derived from protein breakdown are efficiently utilized to maintain protein synthesis, as we have previously demonstrated (10, 18). This retention of nitrogen during fasting, when combined with the anabolic stimulus of a meal alone (4, 25), may lead to muscle (LBM) accretion over time and explain the anabolic effects of chronic testosterone administration.

In summary, the present study demonstrates that careful and near-physiological testosterone administration in older men will increase LBM and muscle strength similarly to younger men. However, further consideration should be given to the specific androgen and length and type of administration regimen to be used in older men and to large-scale studies initiated to determine the risk-to-benefit ratio of testosterone administration in older men.

Oral Testosterone in Oil Plus Dutasteride in Men: A Pharmacokinetic Study

John K. Amory and William J. Bremner

Center for Research in Reproduction and Contraception, Divisions of General Internal Medicine and Endocrinology, Metabolism, and Nutrition, University of Washington Medical School, Seattle, Washington 98195

Testosterone (T) is not administered orally, because it has been reported to be rapidly metabolized by the liver. We hypothesized that sufficient doses of T or T enanthate (TE), administered orally in oil, would result in clinically useful elevations in serum T. We also hypothesized that coadministration of dutasteride (D) with T or TE would minimize increases in serum DHT seen previously with oral administration. Therefore, we conducted a pharmacokinetic study of oral T and TE in oil, with and without concomitant D, in normal men whose T production had been temporarily suppressed by the GnRH antagonist acyline. Thirteen healthy men (mean age, 24 ± 6 yr) were enrolled and assigned to oral T ($n = 7$) and oral TE ($n = 6$) groups and were administered 200, 400, or 800 mg of either T or TE in sesame oil in the morning on 3 successive days 24 h after receiving acyline. Blood samples for measurement of serum T and dihydrotestos-

terone were obtained before T or TE administration and 0.5, 1, 2, 4, 6, 8, 10, 12, and 24 h after administration. Subjects were then administered D for 4 d before repeating the sequence of T or TE doses with D. Serum T was significantly increased in a dose-dependent fashion with the administration of oral T or TE in oil. Coadministration of D with oral T or TE significantly increased the 24-hr average serum T levels compared with administration of T or TE alone [average serum T after 400 mg dose, 8.7 ± 3.0 nmol/l (T) and 8.3 ± 5.7 nmol/l (TE) vs. 16.1 ± 5.8 nmol/l (T + D) and 15.0 ± 8.8 nmol/l (TE + D); $P < 0.05$ for T vs. T and D]. The administration of oral T or TE in oil combined with D results in unexpected and potentially therapeutic increases in serum T. Additional studies of this combination as a novel form of oral androgen therapy are warranted. (*J Clin Endocrinol Metab* 90: 2610–2617, 2005)

TESTOSTERONE (T) IS crucial for male health. The normal male testes produce 4–8 mg T daily (1, 2). Depending on age, 2.5–10% of men have T levels below the normal range (3). T has effects on a variety of tissues, including brain, liver, muscle, bone and bone marrow, blood vessels, skin, prostate, and penis. Men with T deficiency have symptoms of depression, reduced libido, and low energy and suffer from anemia, osteoporosis, and debilitating muscle weakness. These men require T replacement therapy to improve well-being, maintain bone and muscle mass, and retain healthy sexual function (4–8), yet there is no acceptable form of oral T for therapy in the United States.

Most T regimens in the United States depend on parenteral injections, skin patches, gels, or buccal tablets (9–11), because currently available oral forms of T are alkylated and cause liver toxicity when used long term (11–16). Injections are administered im every 1–3 wk and can be painful (17). Some T patches can cause moderate to severe skin reactions due to the vehicle that facilitates T absorption across the skin (18). The T gels are effective and generally well accepted by patients, but are expensive, and care must be taken to avoid inadvertent exposure to women and children (19).

Oral administration of unmodified T at doses up to 100 mg have little effect on serum T levels in T-deficient men (20, 21); however, 200-mg doses of oral T have been shown to elevate

serum T levels to the low normal range for up to 8 h (22, 23). At the time, these serum T levels were thought to be insufficient for clinical use, and research into using unmodified oral T was largely abandoned.

Testosterone undecanoate (TU) is a T ester currently given orally in oil and used clinically in Europe and Canada for the treatment of T deficiency. When administered orally, TU therapy results in therapeutic increases in serum T; however, it also results in elevations in serum dihydrotestosterone (DHT) well above the normal range (24–27). Because DHT is required for cell growth within the prostate, concern has been raised about the potential for long-term harm associated with oral TU therapy from the elevated levels of serum DHT; however, no increased risk of prostate disease has been reported to date.

Because the androgen TU is absorbed well in oil, we believed that other androgens such as T enanthate (TE) and potentially T itself might be well absorbed if also administered orally in oil. Moreover, because the recently available 5α -reductase inhibitor, dutasteride (D), lowers serum DHT levels more than 90% by inhibiting both isozymes of 5α -reductase (28), we hypothesized that oral administration of the combination of higher doses of unmodified T or the T ester, TE, in oil when combined with D would be safe and result in therapeutic serum T levels. In addition, we hypothesized that the concomitant administration of the 5α -reductase inhibitor D with T or TE would further increase serum T levels while minimizing the elevations in serum DHT seen after oral administration of oral androgens such as TU. If effective, we believed that this novel means of T therapy would allow for selective androgen therapy in men with T

deficiency. Therefore, we conducted a pilot study of the oral administration of single doses of T and TE with and without concomitant administration of D to determine the pharmacokinetics and safety of single high doses oral T in oil in healthy men rendered temporarily hypogonadal with the GnRH antagonist acyline.

Materials and Methods

Subjects

Fourteen healthy, normal male volunteers between 18 and 45 yr of age were recruited through local news media (newspaper and radio) and college campus bulletin boards and enrolled in the study. The inclusion criteria were no prior medical illnesses, normal physical examination, and routine hematology, blood chemistry, and liver function. Exclusion criteria included regular use of any medication; abnormal serum T, DHT, or estradiol (E2); or previous or current ethanol, illicit drug, or anabolic steroid abuse. A total of 16 men were evaluated for eligibility. Of these, 14 men were potentially eligible and agreed to participate in the study. The two men who did not enroll in the study were excluded for elevated bilirubin (one subject) and use of finasteride (for the treatment of male-pattern baldness). One enrolled subject failed to appear for his acyline injection and was therefore not studied further; thus, 13 men completed the study period. The institutional review board of University of Washington approved all study procedures, and subjects gave written informed consent before screening.

Study design

Participants were randomly assigned to one of two groups: 1) oral T in sesame oil, or 2) oral TE in sesame oil (Delatestryl, BTG Pharmaceuticals, Iselin, NJ) at a concentration of 200 mg/ml. A sample size of seven subjects per group was estimated to have an 80% power with an α of 0.05 to detect a 50% in the change in serum T area under the curve between a given dose of T and T plus D or between TE and TE plus D. The oral T in sesame oil was manufactured by the compounding pharmacy at University of Washington. Briefly, micronized T (U.S.P. grade, Spectrum Quality Projects, Gardena, CA) was suspended at 100 mg/ml in sesame oil (N.F. grade, Spectrum Quality Projects) and mixed thoroughly on a magnetic stir plate to create a homogenous T/sesame oil emulsion. The compounding pharmacist then drew up the emulsion into syringes at the desired dose levels (200, 400, and 800 mg) immediately before treatment. The syringe was sent to the Clinical Research Unit, where it was vigorously mixed (by shaking) with milk and administered to the subject. The dose of oral TE in sesame oil was normalized for the T content, so that the subjects in the TE group (molecular weight, 397) were administered 276, 554, and 1108 mg TE, corresponding to 200, 400, and 800 mg T.

The drug exposure period lasted 11 d (Fig. 1). On d 0, subjects received a single injection of the GnRH antagonist acyline (300 μ g/kg, sc), which has been shown to suppress T production in normal men for a minimum of 15 d (29). One, 2, and 3 d after acyline administration, subjects drank 200, 400, or 800 mg T or 276, 554, or 1108 mg TE. Subjects self-administered D (0.5 mg, orally, once daily) on d 5–10 after acyline injection, and doses of T and TE were repeated on days 8, 9, and 10. For safety, subjects

underwent daily testing of liver function (aspartate aminotransferase, bilirubin, and alkaline phosphatase), kidney function (urea nitrogen and creatinine), and hemopoiesis (hemoglobin and hematocrit).

Measurements

After treatment on d 1, 2, 3, 8, 9, and 10, subjects had blood drawn via a heparin-locked iv line at 30 min and 1, 2, 4, 6, 8, 10, 12, and 24 h for measurement of serum T, DHT, E2, and SHBG. Total T was measured by a RIA (Diagnostic Products Corp., Webster, TX). The assay had a sensitivity of 0.35 nmol/liter; interassay variations for low, medium, and high pools of 13.6%, 6.1%, and 6.8%, respectively; and intraassay variations of 10.0%, 5.3%, and 6.6%. The normal range was 8.7–33 nmol/liter. DHT was measured using an RIA kit (Diagnostic Systems Laboratory, Inc., Los Angeles, CA). The sensitivity of this assay was 0.043 nmol/liter, and the intraassay variations for medium and low range pools were 9.9% and 11%, respectively, with interassay coefficients of variations of 19% and 25%. The normal range for serum DHT was 1.0–2.9 nmol/liter. SHBG was measured by RIA (Delphia, Wallac Oy, Turku, Finland). The sensitivity of this assay was 0.2 nmol/liter, and the interassay variations for low, medium, and high pools were 31%, 10.6%, and 6.8%, respectively; the intraassay variations were 3.8%, 1.7%, and 2.2%. The normal range was 3.2–47 nmol/liter. The normal ranges for T, DHT, and SHBG were determined in our laboratory using serum samples obtained from 100 normal men, aged 20–50 yr. Serum E2 was measured in the laboratory of Dr. David Hess (Oregon National Primate Research Center, Portland, OR) with an Elecsys 2010 Platform (Roche, Indianapolis, IN). The sensitivity of this assay was 5.5 pmol/liter, intraassay variations were 3.7%, and 2.8% for medium and high range values, and the interassay coefficient of variation was 4.7%. The normal range for serum E2 in this assay in men was 40–220 pmol/liter.

Statistics

Serum hormone levels at each time point for each dose of T or TE with or without D were compared using a Wilcoxon sign-rank test. Pharmacokinetic parameters between successive doses of T or TE with or without D were compared using a Wilcoxon sign-rank test with a Bonferroni correction for repeated measures (effective α = 0.01). The average concentration during the 24-h period after treatment, the maximum concentration after dosing, time to maximum concentration, area under the curve, and elimination phase half-life ($t_{1/2}$) were calculated using a pharmacokinetics program (PK Solutions, Golden, CO). Statistical analyses were performed using STATA (College Park, TX).

Results

Subjects

Fourteen men were enrolled in the study; seven were randomized to the T group, and seven were randomized to the TE group, but one man assigned to the TE group failed to report for his acyline injection. Therefore, seven men completed the T arm, and six completed the TE arm of the study (Table 1). Except for the subject who failed to appear for his acyline injection, all subjects completed the drug exposure

FIG. 1. Study design.

period. There were no serious adverse effects during the study. Nine of the subjects experienced transient mild pruritis at the site of the acyline injection, which resolved in all cases within 1 h of the injection. Eight subjects complained of mild, transient hot flash symptoms toward the end of the study period, presumably due to low T levels; however, no subject complained of feelings of anger, aggression, or irritability during treatment. There were no adverse gastrointestinal symptoms associated with oral T or oral TE in oil. One subject developed a small area of gynecomastia ($<1 \times 1$ cm) immediately under the nipple during the treatment period, but this resolved during follow-up. There were no changes in serum markers of liver or kidney function or in

the hematocrit or hemoglobin during the treatment phase or at follow-up. Furthermore, no significant changes in blood pressure or pulse were observed. T and gonadotropin levels returned to baseline in all subjects during the follow-up period (data not shown). No subjects were lost to follow-up.

Serum T

All subjects were suppressed to castrate levels of T by 24 h after acyline administration (d 0 T, 20.0 ± 7.4 ; d 1 T, 2.3 ± 0.5 nmol/liter; $P < 0.0001$). There was no difference in serum T levels 24 h after acyline between groups [2.3 ± 0.7 (T) vs. 2.3 ± 0.8 (TE); $P = 0.9$]. In addition, mean serum T levels before

FIG. 2. Serum T concentrations (mean \pm SEM) after oral administration of 200, 400, and 800 mg T in oil (A–C) and TE in oil (D–F) with and without D for 24 h in normal men treated with the GnRH antagonist acyline to temporarily suspend T production. Note the larger y-axis for the 800-mg dose. The dotted lines represent the upper and lower limits of the normal range for serum T. *, $P < 0.05$ compared with T alone.

^c $P < 0.01$ vs. T only.

each dose of T were not significantly different from those 24 h after acylone administration.

With the administration of both oral T and oral TE in oil, serum T was significantly increased in a dose-dependent fashion (Fig. 2; $P < 0.01$ for trend). In addition, the maximum concentrations of T, average concentrations of serum T, and area under the curve of serum T increased significantly in a dose-dependent fashion (Table 2 and Fig. 3A), with the maximum concentration of T after oil dosing exceeding the normal range for the 800-mg dose of T and the 400- and 800-mg doses of oral TE in oil. The time of maximum concentration was between 2.5 and 4.5 h in all cases, and the calculated terminal $t_{1/2}$ of oral T and TE in oil was between 7.5 and 11 h.

Coadministration of D with oral T or TE in oil significantly

increased the resulting serum T levels compared with administration of T or TE alone (Fig. 2; $P < 0.01$ for trend). The maximum concentration of T after oral treatment with the combination of T or TE and D exceeded the normal range for both the 400- and 800-mg doses of T and TE in oil. Similar to the administration of T or TE only, the time to maximum concentration remained between 2.5 and 4.5 h, and the calculated terminal $t_{1/2}$ was between 8 and 10 h. The T area under the curve for the combination of T and D was significantly increased at all doses compared with that for T alone [200 mg, 124 ± 28 nmol-h/liter (T alone) vs. 176 ± 45 nmol-h/liter (T + D); 400 mg, 208 ± 74 nmol-h/liter (T alone) vs. 393 nmol-h/liter (T plus D); 800 mg, 328 ± 82 nmol-h/liter (T alone) vs. 846 ± 363 nmol-h/liter (T plus D); $P < 0.01$ for all comparisons].

Serum DHT levels

Serum DHT decreased significantly 24 h after acylone administration (d 0 DHT, 1.6 ± 0.6 nmol/liter; d 1 DHT, 0.6 ± 0.2 nmol/liter; $P < 0.05$). There was no difference in serum DHT levels 24 h after acylone administration between groups (T, 0.5 ± 0.2; TE, 0.6 ± 0.2; $P = 0.63$).

The administration of both oral T and oral TE in oil significantly increased serum DHT in a dose-dependent fashion (Fig. 4). In addition, the maximum concentration of DHT and the area under the curve increased significantly (Table 3), with the maximum concentration of DHT after oral treatment exceeding the normal range for all doses of T and TE in oil. The time of maximum concentration was between 3.9 and 6 h in all cases, and the calculated terminal $t_{1/2}$ of oral T and TE in oil was between 7.5 and 11 h.

Coadministration of D with oral T or TE in oil significantly decreased both maximum and average serum DHT levels compared with the administration of T or TE alone (Fig. 3B and Table 3). The maximum concentration of DHT after oral treatment with the combination of T and D exceeded the normal range at the 800-mg dose of T and at the 400- and 800-mg doses of TE in oil. The time to maximum concentration was between 2.5 and 7.5 h, and the calculated terminal $t_{1/2}$ was between 8 and 10 h. The DHT area under the curve

FIG. 3. Average serum T (A) and DHT (B) concentrations (mean ± SD) over the 24-h interval after oral treatment. The dotted lines represent the upper and lower limits of the normal range for serum T. *, $P < 0.05$ compared with T alone.

FIG. 4. Serum DHT concentrations (mean \pm SEM) after oral administration of 200, 400, and 800 mg T in oil (A–C) and TE in oil (D–F) with and without D for 24 h in normal men treated with the GnRH antagonist acyline to temporarily suspend T production. Note the larger y-axis for the 800-mg dose. The dotted lines represent the upper and lower limits of the normal range for serum DHT. *, $P < 0.05$ compared with T plus D.

for the combination of T and D was significantly decreased compared with the area under the curve for T alone at all doses.

Serum E2 and SHBG

Mean serum E2 levels were not significantly different between the treatment groups on d 0 [134 ± 21 (T) vs. 116 ± 30 (TE) pmol/liter] or 24 h after acyline administration [94 ± 14 (T) vs. 87 ± 12 (TE) pmol/liter]. With oral administration of T or TE, serum E2 levels increased nonsignificantly compared with baseline levels with the 800-mg dose in both the T and TE groups (Fig. 5), but all E2 levels remained within the normal range. There were no significant differences in

serum E2 between either T or TE alone compared with T or TE with D coadministration. Serum SHBG did not change significantly after administration of acyline or oral administration of T or TE in oil either with or without concomitant D administration (Fig. 6).

Discussion

In this study we have demonstrated that single doses of T or TE when administered orally in oil can result in serum T levels that would be useful for the treatment of T deficiency. Secondly, we have demonstrated that addition of the 5 α -reductase inhibitor D to oral T in oil 1) significantly increases the serum T levels achieved after a given dose of T, and 2)

attenuates the supraphysiological elevations in serum DHT seen with the administration of oral T or T esters (e.g. TU) without concomitant 5 α -reductase inhibition.

These data contradict the prevailing wisdom in the field, which states that the oral route for T delivery is impractical

due to near-complete hepatic first-pass metabolism of orally administered T (11). Although it is true that the bioavailability of orally administered T is very low, probably around 1% (30, 31), our work demonstrates that if sufficient T is administered orally in oil, potentially therapeutic levels of serum T can be achieved after oral dosing. It is likely that liver metabolism of orally dosed T is extensive, because oral T administered to men with cirrhosis results in serum T levels that are markedly elevated compared with normal controls (32, 33). Whether long-term administration of oral T in oil would induce increased hepatic metabolism of oral T and therefore reduce T bioavailability will be the subject of future research.

Previous studies of the oral administration of T may have found reduced levels of serum T in part due to 5 α -reductase activity in the intestine and liver (34). In this study using T or TE, and in the work of others with TU (24–27), serum levels of DHT after oral administration are markedly elevated, implying that a large fraction of the orally adminis-

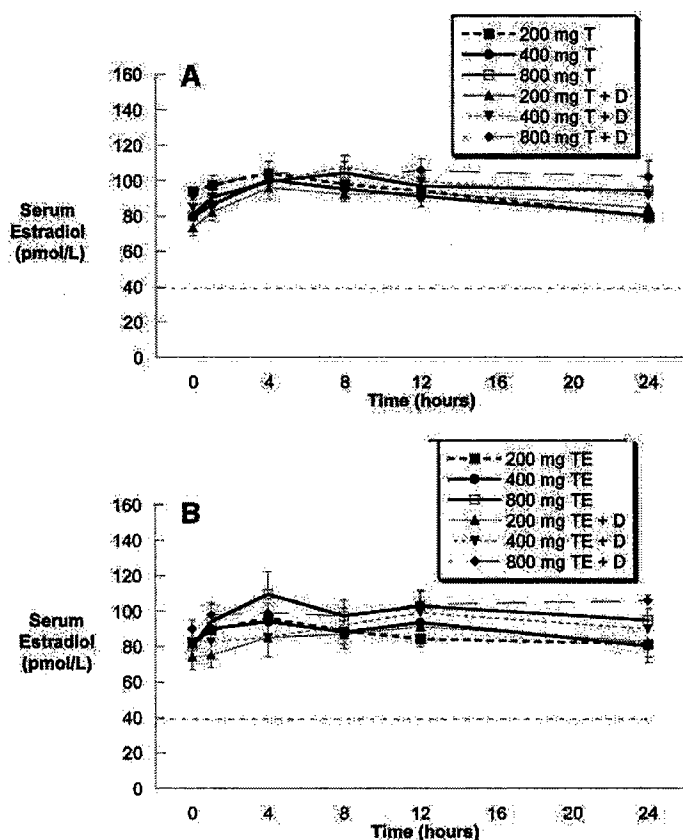

FIG. 5. Serum E2 (mean ± SEM) after oral administration of 200, 400, and 800 mg T (A) and TE (B) in oil with and without D for 24 h in normal men treated with the GnRH antagonist acyline to temporarily suspend T production. The dotted line represents the lower limit of the normal range.

FIG. 6. Serum SHBG concentrations (mean ± SEM) after oral administration of 200, 400, and 800 mg T and TE in oil with and without D for 24 h in normal men treated with the GnRH antagonist acyline to temporarily suspend T production. The dotted lines represent the upper and lower limits of the normal range.

tered T dose may be metabolized in the liver and intestines to DHT. Surprisingly, in this study, the coadministration of a 5 α -reductase inhibitor roughly doubles the average T concentration and the area under the curve for the serum T while reducing the elevations of serum DHT by approximately half. These marked elevations in serum T with concomitant 5 α -reductase inhibition are probably due to inhibition of the 5 α -reductase enzyme in intestine and liver, which appears to account for approximately one half of the metabolism of T after an oral dose. Importantly, the combination of elevated serum T without marked elevations in serum DHT may allow for selective oral androgen therapy, which may be useful in decreasing the risk for DHT-dependent disease, such as benign prostate hyperplasia and prostate cancer.

It is also important to note that previous studies of oral T administration demonstrating poor oral bioavailability of T have used T in powder form at doses of 100 and 200 mg (21–23). We have tested oral T in powder form in doses as high as 400 mg without achieving therapeutic serum T levels (data not shown), implying that the administration of T in oil is crucial for the achievement of the therapeutic serum T levels seen in this study. It has been previously shown that the absorption of oral TU is markedly affected by concomitant intake of fatty foods (27, 30). This is probably due to the fact that much of the orally administered TU is absorbed via the lymphatics (35). In an animal model of TU absorption, more than 80% of the bioavailable T is thought to be absorbed via the lymphatics (36). Whether food intake will affect the absorption of oral T in oil is unknown and probably depends on how much of the dose is absorbed via lymphatics *vs.* via the portal circulation. Because T was administered in oil in this study, some of the dose may have been absorbed via the lymphatics. This might explain in part the unexpectedly long serum half-life of T seen with oral compared with iv administration of T, which has been reported to have a half-life of less than 1 h (31, 37). Another possibility is that there is some degree of enterohepatic circulation of the orally administered T, prolonging the apparent half-life in serum. Because of this uncertainty, the impact of food intake on the absorption and serum levels of T after the administration of oral high dose T will be the subject of future study.

It is important to note that there was no evidence of either liver or kidney toxicity associated with the doses of oral T administered in this study; however, additional long-term study of these doses combined with a 5 α -reductase inhibitor will be required to determine the safety of this approach to T therapy. Although one subject did report transient gynecomastia, this subject's serum E2 level remained within the normal range. Additionally, no subject complained of impotence, decreased libido, or sexual dysfunction during the treatment period. These side effects have been reported when D is administered alone for benign prostate hyperplasia (38); however, in theory, they would be less likely when D is administered in combination with T. Additionally, the implication of long-term 5 α -reductase inhibition will need examination given the increase in high grade prostate cancer (despite an overall decrease in prostate cancer incidence) seen with chronic finasteride administration in the prostate cancer prevention trial (39).

There were slight, nonsignificant increases in serum E2

seen after oral dosing of T and TE in oil. This implies that although orally administered T can undergo aromatization to E2, it does not do so at high levels, suggesting that there is probably little aromatase activity in the intestine and liver in man. This finding is reassuring in showing that orally administered T is likely to allow for the important functions of estrogen in man, such as maintenance of bone density (40), but not lead to an increased risk of estrogen-related side effects such as gynecomastia.

From a practical standpoint, a regimen using oral T in oil in the formulation used in this study may need to be administered twice daily; however, additional refinements of this approach, such as the use of slow-release capsules, may allow for more controlled release of T in the intestine and could lead to a formulation that could be administered orally once daily, a major improvement over current T replacement options.

In conclusion, we have demonstrated that single doses of T or TE, when administered orally in oil, can result in markedly elevated serum levels of T in normal men with induced hypogonadism; such levels would presumably be therapeutically effective in treating testicular failure. In addition, we have demonstrated that addition of the 5 α -reductase inhibitor D to oral T in oil significantly increases the serum T levels observed with a given dose of T and attenuates the supraphysiological elevations in serum DHT seen with the administration of oral T alone. Combinations of oral T and 5 α -reductase inhibitors may allow for an oral, selective form of androgen therapy. Additional studies of the long-term safety, pharmacokinetics, and pharmacodynamics of this combination are warranted to determine whether it might be a clinically useful and attractive method of treating T deficiency.

Acknowledgments

We acknowledge Ms. Amanda Wiseman for assistance with study implementation, and Ms. Dorothy McGuinness for performing the hormone assays.

Exogenous Testosterone or Testosterone with Finasteride Increases Bone Mineral Density in Older Men with Low Serum Testosterone

JOHN K. AMORY, NELSON B. WATTS, KIRK A. EASLEY, PAUL R. SUTTON,
BRADLEY D. ANAWALT, ALVIN M. MATSUMOTO, WILLIAM J. BREMNER, AND J. LISA TENOVER

Departments of Medicine (J.L.T.) and Biostatistics (K.A.E.), Emory University School of Medicine, Rollins School of Public Health, Atlanta, Georgia 30329; Department of Medicine (N.B.W.), University of Cincinnati College of Medicine, Cincinnati, Ohio 45267; and Department of Medicine (J.K.A., P.R.S., B.D.A., A.M.M., W.J.B.), Veterans Affairs-Puget Sound Health Care System (B.D.A. and A.M.M.), and Geriatric Research, Education and Clinical Center (A.M.M.), University of Washington School of Medicine, Seattle, Washington 98195

Older men, particularly those with low serum testosterone (T) levels, might benefit from T therapy to improve bone mineral density (BMD) and reduce fracture risk. Concerns exist, however, about the impact of T therapy on the prostate in older men. We hypothesized that the combination of T and finasteride (F), a 5 α -reductase inhibitor, might increase BMD in older men without adverse effects on the prostate. Seventy men aged 65 yr or older, with a serum T less than 12.1 nmol/liter on two occasions, were randomly assigned to receive one of three regimens for 36 months: T enanthate, 200 mg im every 2 wk with placebo pills daily (T-only); T enanthate, 200 mg every 2 wk with 5 mg F daily (T+F); or placebo injections and pills (placebo). Low BMD was not an inclusion criterion. We obtained serial measurements of BMD of the lumbar spine and hip by dual x-ray absorptiometry. Prostate-specific antigen (PSA) and prostate size were measured at baseline and during treatment to assess the impact of therapy on the prostate. Fifty men completed the 36-month protocol. By an intent-to-treat analysis including all men for as long as they contributed data, T therapy for 36 months increased BMD in these men at the lumbar spine [$10.2 \pm 1.4\%$ (mean percentage increase from baseline \pm SEM; T-only) and $9.3 \pm 1.4\%$ (T+F) vs. $1.3 \pm 1.4\%$ for placebo ($P < 0.001$)] and in the hip [$2.7 \pm 0.7\%$ (T-only) and $2.2 \pm 0.7\%$ (T+F) vs. $-0.2 \pm 0.7\%$ for placebo, ($P \leq 0.02$)]. Significant

increases in BMD were seen also in the intertrochanteric and trochanteric regions of the hip. After 6 months of therapy, urinary deoxypyridinoline (a bone-resorption marker) decreased significantly compared with baseline in both the T-only and T+F groups ($P < 0.001$) but was not significantly reduced compared with the placebo group. Over 36 months, PSA increased significantly from baseline in the T-only group ($P < 0.001$). Prostate volume increased in all groups during the 36-month treatment period, but this increase was significantly less in the T+F group compared with both the T-only and placebo groups ($P = 0.02$). These results demonstrate that T therapy in older men with low serum T increases vertebral and hip BMD over 36 months, both when administered alone and when combined with F. This finding suggests that dihydrotestosterone is not essential for the beneficial effects of T on BMD in men. In addition, the concomitant administration of F with T appears to attenuate the impact of T therapy on prostate size and PSA and might reduce the chance of benign prostatic hypertrophy or other prostate-related complications in older men on T therapy. These findings have important implications for the prevention and treatment of osteoporosis in older men with low T levels. (*J Clin Endocrinol Metab* 89: 503–510, 2004)

TWENTY PERCENT OF men over age 60 have serum testosterone (T) concentrations below the normal range for young men (1, 2). Because low T levels are associated with an increased risk of osteoporosis and fracture (3–7), T therapy in older men might increase bone mineral density (BMD) and reduce fracture risk. Studies in young, hypogonadal men have demonstrated that T therapy increases BMD (8–11), but few studies have investigated older patients, who are at greater risk of fracture. Two randomized clinical trials of transdermal T treatment in men over the age of 64 yr have been published (12, 13). In the first study, vertebral but not hip BMD increased, and only in those with low pretreatment

T levels (12). In the second study, T prevented the loss of hip BMD observed in the placebo-treated men (13). Therefore, significant questions still exist about the ability of T therapy in older men to have significant impact on bone health.

The relative roles of T and its metabolite, dihydrotestosterone (DHT), in regulating BMD are not clear. Because DHT contributes to the development of benign prostatic hypertrophy (BPH) and possibly prostate cancer, increasing T levels without also increasing DHT might be preferable in older men, especially if DHT has little or no effect on BMD. Finasteride (F) inhibits DHT production by blocking the enzyme 5 α -reductase, which converts T to DHT, and has been used safely to treat BPH in older men without compromising BMD (14–16).

We hypothesized that long-term im T therapy in older men who had serum T below the range of normal for young adult men would significantly increase BMD. Furthermore, we hypothesized that the addition of the 5 α -reductase inhibitor F would have no impact on T-mediated increases in BMD but

Abbreviations: BMD, Bone mineral density; BPH, benign prostatic hypertrophy; CV, coefficient of variation; DHT, dihydrotestosterone; E2, estradiol; F, finasteride; po, per os; PSA, prostate-specific antigen; T, testosterone; TE, T enanthate.

JCEM is published monthly by The Endocrine Society (<http://www.endo-society.org>), the foremost professional society serving the endocrine community.

would minimize the potential for adverse effects on prostate health. Therefore, we conducted a randomized, double-blind, placebo-controlled trial of im T administration, with or without F, to test these hypotheses.

Subjects and Methods

Subjects

Men aged 65 yr and older were recruited using advertisements and direct mailings. The inclusion criterion was a nonfasting, morning serum total T level below 12.1 nmol/liter (350 ng/dl) for 2 d. Exclusion criteria included the following: severe illness; use of medications including anabolic steroids, antiandrogens, glucocorticoids, bisphosphonates, diuretics, calcitonin, seizure medications, or warfarin; Paget's disease; smoking or heavy alcohol use; sleep apnea; hematocrit greater than 48%; total cholesterol above 300 mg/dl; abnormal kidney, liver, thyroid, adrenal, or pituitary function; regular exercise more than three times a week; prostate issues [prostate cancer, a prostate nodule on exam, prostate-specific antigen (PSA) >4.0 ng/ml, or International Prostate Symptom Score >8]; urinary postvoid residual by ultrasound of more than 149 ml; or an abnormal transrectal ultrasound. Reduced BMD was not an inclusion criterion. The Institutional Review Board of Emory University, where all subject interactions occurred, approved the study, and subjects gave written informed consent before screening.

A total of 676 men were evaluated for eligibility. Of these, 283 men were potentially eligible and underwent T measurement. One hundred ten men met the T criterion and underwent further screening tests; 70 men were enrolled. Forty men who passed initial screening were not enrolled for the following reasons: abnormal PSA, prostate ultrasound, postvoid residual, or symptom score (11); pituitary, thyroid, or adrenal disease (5); medical illness (4); second T levels above 350 ng/dl (4); total cholesterol above 300 mg/dl (1); or being eligible but refusing enrollment (15).

Study design

Participants were randomized to one of three treatment groups: 1) T-only group, T enanthate (TE; Schein Pharmaceuticals, Florham Park, NJ) 200 mg im every 2 wk, plus placebo pill orally [*per os* (po)] daily; 2) T+F group, TE 200 mg im every 2 wk, plus F (Merck & Co., Rahway, NJ) 5 mg po daily; or 3) placebo group, sesame oil placebo 1 ml im every 2 wk, plus placebo pill po daily. The estimate of sample size for the trial was based on the percentage change in BMD from baseline to 6-month follow-up. Assuming a clinically important increase on average of 1% in the T+F group, no change on average in the placebo group, and an estimated SD in each group of 1%, a sample size of 17 men per group ensured approximately 80% statistical power to detect a treatment difference of 1% (significance level, 0.05; two-sided test) if the true difference between groups was a 1% BMD increase from baseline to 6-month follow-up. Allowing for a 30% dropout rate over 3 yr, 70 patients were randomized in the trial.

The order of treatment assignment was randomly computer-generated in permuted blocks of six. Participants were treated for 36 months. Only the research pharmacist and safety monitoring board knew of the randomization. A nurse administered the injections, and 98% occurred within 2 d of the scheduled time. There was 95% compliance with the daily F or placebo in the enrolled subjects based on monthly pill counts. The study design included the potential for dose reduction of T or placebo injection by decrements of 0.2 ml (40 mg of TE for subjects actually receiving T) for a hematocrit of more than 52% on safety monitoring performed at 2, 4, 8, 12, 18, 24, and 30 months. Calcium and vitamin D supplements were not provided, but patients were allowed to continue these medications if they were taking them already. Participants were queried at the beginning and end of the study in regard to the intake of these supplements, with no significant change in their use being noted. Specifically, two men in the placebo group, one man in the T-only group, and none in the T+F group were taking calcium supplements during the study. No subject was taking additional vitamin D.

For men who discontinued the study prematurely, telephone follow-up was conducted to ascertain clinical outcomes.

Measurements

At baseline and after 6, 12, 18, 24, and 36 months of treatment, BMD was measured at the lumbar spine (L1-L4; anteroposterior view only) and in the nondominant hip by dual x-ray absorptiometry using a Hologic QDR-2000 densitometer (Hologic, Waltham MA) that was standardized daily. The intraperson coefficient of variation (CV) was 1.0% for both the spine and the hip. T and Z scores were calculated using male databases; the manufacturer's database was used for the spine, and the National Health and Nutrition Examination Survey III was used for all of the hip measurements. One of the investigators (N.B.W.) who was blinded to treatment analyzed all of the BMD measurements and excluded from analysis vertebrae that showed localized degenerative change, compression fractures, or other confounding factors. One or two vertebrae were deleted from analysis if there was obvious degenerative change on the image and/or if it was 1 SD or more higher than the lowest vertebrae (six placebo subjects, five T-only subjects, and five T+F subjects). If three or more vertebrae showed evidence of degenerative change, the spine measurement was considered invalid and was not used (no placebo subjects, two T-only subjects, and one T+F subject).

Blood was drawn for hormone measurements in the morning at baseline and immediately before injections after 2, 4, 6, 8, 12, 18, 24, 30, and 36 months of treatment. Samples at baseline 6, 12, 18, 24, and 36 months were fasting samples, whereas the other samples were nonfasting. Blood was drawn for markers of bone metabolism after a 12-h fast at baseline and after 6 months of treatment. For a subset of men ($n = 22$), additional morning blood was drawn at the end of the first study year on d 3 or 4, 7, and 11 of the T-dosing period to obtain between-nadir samples. Serum samples for 25-hydroxyvitamin D and intact PTH were assayed immediately. All other samples were stored frozen at -70°C until the end of the study, when serum samples from each participant were assayed concurrently. A 2-h morning urine was collected for measurement of deoxypyridinoline at baseline and after 6 months of treatment. T, SHBG, and estradiol (E2) were measured using fluoroimmunoassays (Delfia, Wallac Oy, Turku, Finland). The intraassay and interassay CVs for midrange measurements were 4.5 and 9.5% for T, 4.0 and 11.1% for SHBG, and 3.6 and 6.0% for E2. The normal range is 12–33 nmol/liter for T and 60–220 pmol/liter for E2. DHT was measured by RIA (Endocrine Sciences, Calabasas Hills, CA); the midrange intraassay and interassay CVs were 6.6 and 14%, respectively. Non-SHBG-bound, bioavailable T was assayed using RIA after ammonium sulfate precipitation [Centre Hospitalier de l'Université at Laval University (CHUL) Research Center, Sainte-Foy, Quebec, Canada]; the midrange intraassay and interassay CVs were 7.4 and 12%, respectively. Osteocalcin was measured by RIA (Diagnostic Systems Laboratories, Inc., Webster, TX); the midrange intraassay and interassay CVs were both 7.2%. Bone-specific alkaline phosphatase was measured by immunoassay (Metra Biosystems, Mountain View, CA); the midrange intraassay and interassay CVs were 1.4 and 4.8%, respectively. Urinary deoxypyridinoline was measured by chromatography after acid hydrolysis and was normalized to urinary creatinine; midrange intraassay and interassay CVs were 8 and 15%, respectively. Intact PTH was measured by a chemiluminescent assay (Diagnostic Products Corp., Los Angeles, CA); midrange intraassay and interassay CVs were 5.1 and 5.3%, respectively.

Participant monitoring

Participants were examined monthly. Measurements of hematocrit and transaminases occurred every 2 months for 1 yr, and every 6 months thereafter. Prostate volume was assessed by transrectal ultrasound (Brüel & Kjaer, Borås, Sweden) at baseline (model 3535) and at the end of treatment (model 1846 PM) using established techniques (17, 18). PSA levels were measured every 4 months during the first year and every 6 months thereafter; digital rectal examination was performed every 6 months.

Statistical analysis

The primary analyses of the data were performed according to patients' original treatment assignment (*i.e.* intention-to-treat analyses), and all men were included in the analyses for as long as they contributed data. Baseline characteristics between treatment groups were compared with the Kruskal-Wallis test. Repeated-measures analyses for each of the

four BMD measurements were analyzed as percentage change from baseline with a means model with SAS Proc Mixed (version 8; SAS Institute, Inc., Cary, NC) providing separate estimates of the means by time on the study (6, 12, 18, 24, 30, and 36 months) and treatment groups. An unstructured variance-covariance form among the repeated measurements was assumed for each outcome, and estimates of the SE values of parameters were used to perform statistical tests and construct 95% confidence intervals. Student's *t* tests were used to compare the pairwise differences between the model-based treatment means (least-squares means) at each time point or treatment month. The model-based means are unbiased with unbalanced and missing data, as long as the missing data are noninformative (missing at random). A dropout process is assumed to be missing at random if, depending on the observed data, the dropout is independent of the unobserved measurements. Mean changes over time within a treatment group were tested for linear trend. Repeated-measures analyses were also performed for T, DHT, E2, and PSA after a log transformation, and for prostate volume, hematocrit, hemoglobin, and lipids. The Wilcoxon signed-rank test was used to compare change from baseline to 6 months within each treatment group for six markers of bone metabolism. Statistical tests were two-sided. A Bonferroni adjustment ($P < 0.0167$) was used for the three pairwise comparisons performed at each treatment month.

Results

Seventy men, with a mean age of 71 ± 4 yr (range, 65–83 yr), participated in the study. Twenty-four were randomized to T-only, 22 to T+F, and 24 to placebo. Fifty men completed the entire 36 months of the study. Of the 20 men who did not complete the study, six were in the placebo group, and seven each were in the T-only and T+F groups. Reasons for discontinuation included the following: personal reasons (10 men), intercurrent illness (7 men), or a new diagnosis of

prostate cancer (3 men). At baseline, the three treatment groups did not differ significantly from each other in age, body mass index, hormone levels, BMD, prostate volume, or PSA (Table 1). Twenty-four of the 70 men (10 in the placebo group, 8 in the T-only, and 6 in the T+F group) had baseline serum E2 levels that were below the lower limit of normal. The baseline BMD for the hip and lumbar spine for the participants was similar to that for a standard male population of the same age (Z scores, Table 1). A total of seven men, two each in the placebo and T+F groups and three in the T-only group, had low baseline lumbar-spine BMD (T score more than 2.5 sd below peak bone mass for young men), whereas four men, two in the placebo group and one each in the T-only and T+F groups, had low baseline hip BMD. There were no significant differences in the baseline characteristics between the men who discontinued and those who completed the study. Reduction of T dosage was necessary in 14 men (seven in the T-only group and seven in the T+F group *vs.* none in the placebo group). After the decrease in T dosage, the final mean (\pm sd) dose of TE was 158 ± 36 mg for the T-only group and 164 ± 40 mg for the T+F group every 2 wk.

Mean nadir serum total T, bioavailable T, and E2 levels in the T-only and T+F groups significantly increased throughout the treatment period (Fig. 1, A–C), whereas these hormone levels did not change in the placebo group. Nadir serum total T and E2 levels tended to be higher in the T+F group compared with the T-only group, but this difference

^a T score compares the BMD to the mean for young normal males and Z score compares it with age-matched controls.

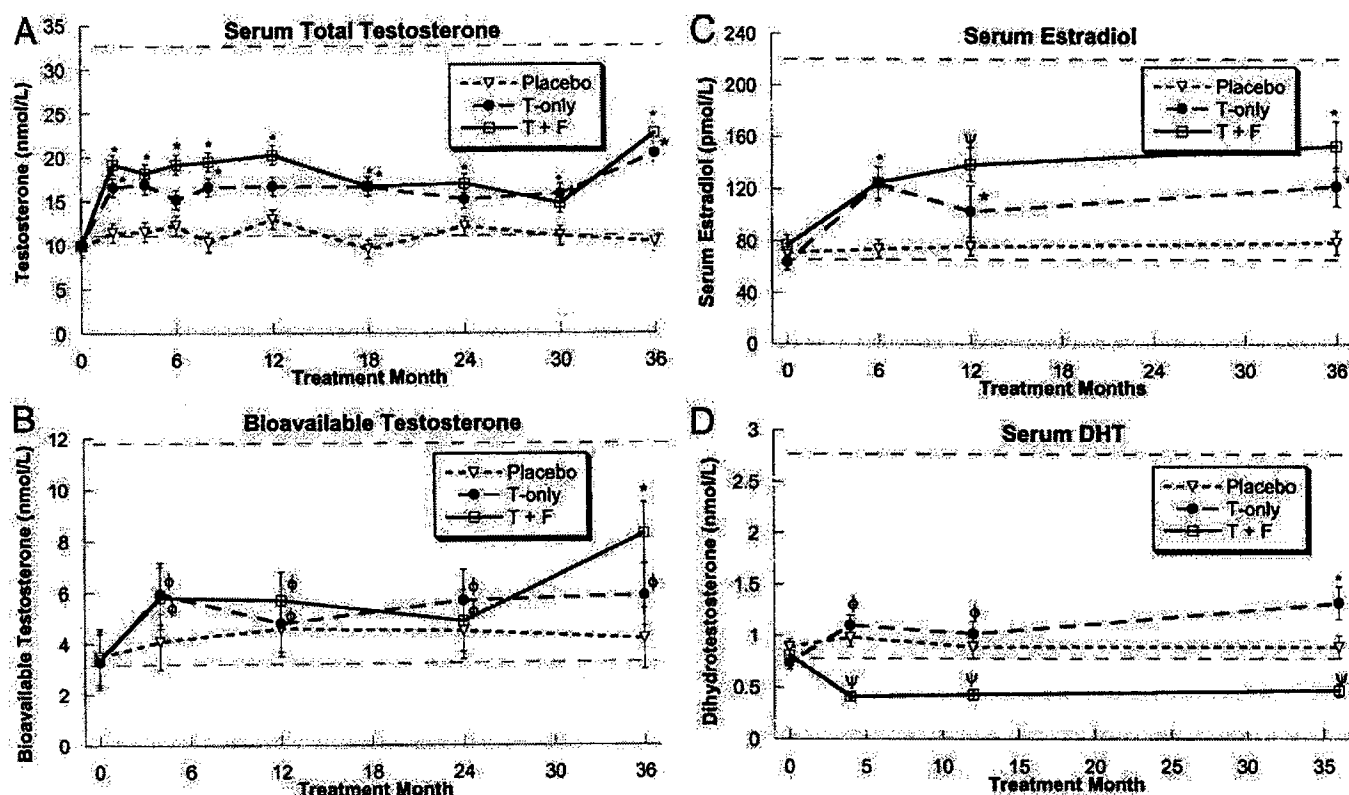

FIG. 1. Geometric mean (\pm SEM) nadir serum total T (A), bioavailable (non-SHBG-bound) T (B), E2 (C), and DHT (D) in older men with low T who were treated with either T (T-only), T and F (T+F), or placebo for 36 months. Horizontal dotted lines represent normal ranges. *, $P < 0.05$ compared with baseline and placebo; ψ , $P < 0.05$ compared with baseline, placebo, and T-only; ϕ , $P < 0.05$ compared with baseline.

did not reach statistical significance for any time point for total T and was only significant at month 12 for E2 ($P = 0.03$). For the subset of men from whom blood was sampled at multiple times throughout the 2-wk T-dosing period (six men in the placebo group, seven men in the T-only group, and nine men in the T+F group), peak serum total T levels were at or above the normal serum T range for the two T treatment groups, with a mean peak value for the T-only group being 35.9 ± 12.1 nmol/liter (mean \pm SD) and that for the T+F group being 43.5 ± 7.6 nmol/liter. Average total T levels during the 2-wk dosing interval were 25.8 ± 6.0 , 33.0 ± 6.4 , and 11.8 ± 2.3 nmol/liter for the T-only, T+F, and placebo groups, respectively. In comparing these two T treatment groups, there was no difference in peak T levels ($P = 0.13$), but the average total T levels were somewhat higher in the T+F group ($P = 0.04$).

Mean nadir serum DHT levels did not change throughout the study in the placebo group, increased significantly in the T-only group, and decreased in the T+F group ($P < 0.001$ compared with baseline and placebo) by 6 months and remained suppressed throughout treatment (Fig. 1D). The maximum decline in serum DHT levels in the T+F group was 50% below baseline, which was reached at treatment month 4.

BMD and metabolism

BMD of the lumbar spine, total hip, and trochanteric and intertrochanteric regions increased in both the T-only and the

T+F groups during the study period, whereas those in the placebo group did not change ($P < 0.001$; Table 2 and Fig. 2, A–D). The mean percentage increase from baseline in BMD of the lumbar spine was significant ($P < 0.001$) for the T-only and T+F groups, but the mean did not change for men in the placebo group ($P = 0.39$ for linear trend). There was no significant change over the 36 months in the BMD at the femoral neck in any of three treatment groups ($P = 0.16$). In the T groups, increases in lumbar BMD were positively correlated with magnitude of increase in both serum total T ($r = 0.44$; $P = 0.001$), bioavailable T ($r = 0.45$ and $P = 0.009$), and serum E2 ($r = 0.45$; $P = 0.0006$) but were not related to baseline BMD; to baseline levels of total T, bioavailable T, DHT, or E2; or to baseline levels of T or E2 after correction for baseline SHBG levels.

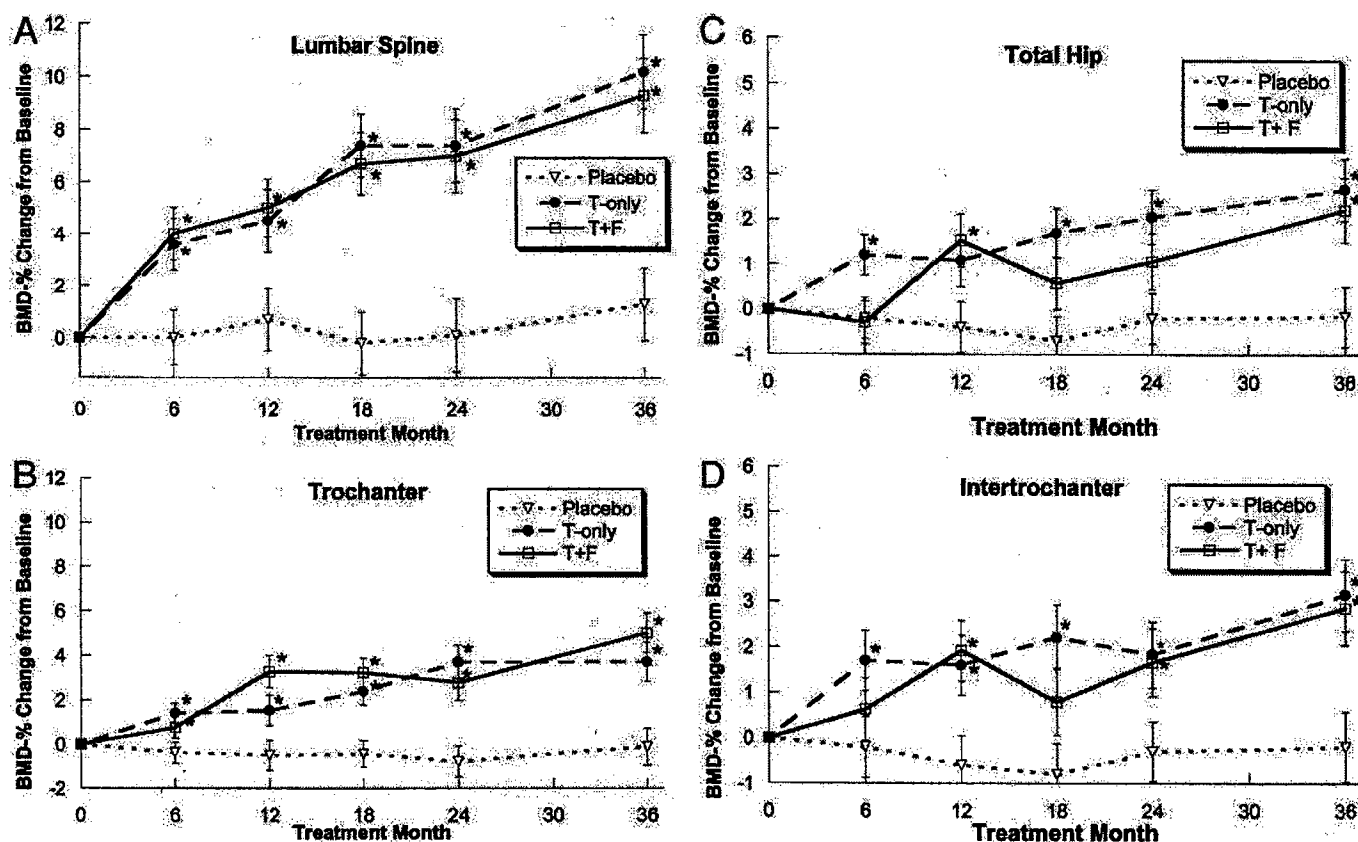

After 6 months of therapy, serum osteocalcin (a bone formation marker), intact PTH, and 25-hydroxyvitamin D did not change in any group (Table 3). In contrast, urinary deoxypyridinoline, a bone resorption marker, decreased significantly in both the T-only and T+F groups (both $P < 0.001$) but was unchanged in the placebo group ($P = 0.30$). Bone-specific alkaline phosphatase, a bone formation marker, decreased significantly in the T-only group ($P = 0.049$).

Prostate and hematological effects

Forty-nine of the 50 subjects who completed the 36-month study underwent end-of-treatment prostate ultrasound, and

crease in prostate volume in the T+F group was significantly less than in the T-only group ($P = 0.02$).

One man in the placebo group, two in the T-only group, and no subjects in the T+F group had a diagnosis of prostate cancer, leading to discontinuation of study participation ($P = 0.46$). The two men with prostate cancer in the T-only group were diagnosed after 7 and 8 months of study participation. The indication for biopsy in one case was an abnormal digital rectal exam and in the other case was asthenia and fever. In both cases, one of six biopsy samples revealed Gleason grade 5 disease. For the man with the abnormal digital rectal exam, the positive biopsy occurred in the opposite lobe from the abnormal exam finding. The individual in the placebo group with prostate cancer was diagnosed after 24 months in the study; the indication for biopsy was an elevated PSA. Of the 17 remaining men who discontinued participation in the study, 15 were free of prostate cancer or other prostate diseases at the conclusion of the study. Two men were lost to follow-up.

Mean hematocrit and hemoglobin values increased significantly during treatment in the T-only and T+F groups ($P < 0.001$ compared with baseline and placebo) but were unchanged in the placebo group (Table 4). Increase in hematocrit was positively associated with elevations in T ($r = 0.41$; $P < 0.001$). In the T-only group, one man suffered a cerebral hemorrhage during treatment, and another man developed new symptoms of sleep apnea confirmed by a sleep study. There were no other serious adverse cardiovascular, cerebrovascular, or pulmonary events.

Discussion

This study demonstrates that im T therapy in older men with low serum total T levels increases BMD in the lumbar spine and hip over 3 yr. The increase in BMD would be expected to decrease fracture risk. The increases in BMD seen in this study are similar in magnitude both to those observed with T therapy in younger hypogonadal men (8–11) and to those seen with bisphosphonate therapy in men with osteoporosis (19, 20). The increases seen in BMD were not limited to the spine but also involved most areas of the hip that were measured. Previous studies of T therapy in older men have reported either smaller increases in lumbar spine BMD (12) or no increase in hip BMD with T therapy (12, 13). There could be a number of reasons why the findings of this study differ from the findings of these previous studies. For one, the men enrolled in this study all had baseline serum total T levels that were below the normal range for young men,

which was not the case in one of the previous studies (12). In addition, the serum levels of total T and E2 achieved with im T injections in this study were two to three times higher than those achieved in studies using T patches in older men (12, 13). Such large increases over baseline T and E2 levels might account for much of the difference between the increases in BMD seen in these studies. Although the dose-response range for bone in regard to T (or E2) in older men has not been established yet, these data may suggest that a certain threshold of serum T (or E2) must be reached and/or a certain magnitude of change from baseline levels must be achieved before significant effects of the sex steroids on bone are achieved in older men. It also is important to note that, in contrast to previous studies in older men, subjects in our study were not administered supplemental calcium and vitamin D. This may have increased the magnitude of the differences between placebo and treatment groups we observed in our study; however, dramatic improvements in BMD were seen without calcium and vitamin D supplementation. Whether supplementation in combination with T would result in even greater increases in BMD should be the subject of future research.

Both the T-only and the T+F groups had similar increases in serum nadir total T and E2 levels and in BMD; however, there was a significant decrease in serum DHT in the T+F group. This suggests that conversion to DHT is not essential for the effect of T on BMD. Because F incompletely blocks the conversion of T to DHT (21) and men in our study achieved at best a 50% reduction in serum DHT levels, it is still possible that low levels of DHT are required for stimulating increases in BMD.

The beneficial effects of T therapy on BMD may be mediated by its conversion to E2. The increases in E2 serum levels from baseline with T therapy in this study were substantial. The impact of E2 on BMD in men has been demonstrated in a man with aromatase deficiency who had high serum T levels but low BMD. Treatment with E2 resulted in epiphyseal closure and increased BMD (22). Furthermore, a second man with an E2 receptor mutation was found to have unfused epiphyses and low BMD (23). Other work has suggested that bioavailable E2 may be the best predictor of BMD in older men (24, 25). Although it is likely that E2 plays a major role in maintenance of BMD in men, further studies using nonaromatizable androgens will be required before we will completely understand relative roles of T and E2 in bone formation in men.

The mechanism by which androgens and/or estrogens

improve BMD is unclear, but androgen receptors have been identified in osteoblasts (26). In our study, most markers of bone formation were unchanged, but the most sensitive marker of bone resorption (27), urinary deoxypyridinoline, decreased significantly. This suggests that T therapy reduces bone resorption more than it increases bone formation. This finding is in agreement with a recently published study in younger men (28). This “antiresorptive” effect of T also might be mediated by E2 (29) and is a main mechanism by which E2 is thought to increase BMD in postmenopausal women (30).

Regarding the prostate, all groups showed increases in prostate volume that were greater than those observed previously in prospective studies of older men (31, 32). The change in ultrasound equipment between baseline and the end of the study may have contributed to the seemingly larger-than-expected magnitude of volume change between baseline and end-of-study. However, because this would have affected equally all treatment groups, the relative volume change differences seen between treatment groups should still be valid. Notably, the T+F group had significantly less increase in prostate volume than either the T-only or placebo groups. The attenuation of prostate volume enlargement seen in this study with the concomitant use of a 5 α -reductase inhibitor, rather than a reduction in prostate volume that is usually reported with such therapy (32), is mirrored by the less-than-expected reduction in serum DHT levels in the T+F group and may have occurred because of the high serum T levels produced by the T-injection regimen used. Nonetheless, this attenuation of prostate growth by 5 α -reductase inhibition might be important in preventing symptomatic BPH and possibly reducing the risk of prostate cancer in older men treated with long-term T therapy; however, our trial lacked sufficient numbers of subjects to detect any possible benefit of F on the risk of these outcomes. Notably, the recently published prostate cancer prevention trial showed a 25% reduction in new cases of prostate cancer in older men treated with F therapy (33). Clearly, larger studies of T therapy with 5 α -reductase inhibitors in older men will be required before a small increased risk of prostatic complications can be excluded.

Subjects in our study did have a higher rate of erythrocytosis than seen in previous trials of T administration in older men using transcutaneous patches (10, 11). Thirty percent of subjects receiving 200 mg of TE every other week in our study developed a hematocrit greater than 52% and required a reduction in the T dose to an average of 158 mg. This finding is probably due to the high serum T levels, especially peak T levels, that were produced in this study and is consistent with rates of erythrocytosis seen in other studies in which older males have been treated with im T (34). Therefore, it is possible that a dose of 150 mg, rather than 200 mg, of TE every 2 wk might be a safer dosage in older men to prevent problematic erythrocytosis; however, there are not data to demonstrate that this dose will prevent bone loss. It is important to note that no ischemic strokes, heart attacks, or episodes of thromboembolism were observed in our study; however, this study lacked sufficient power to rule out a small increase in such events.

In summary, we conclude that T therapy in older men with

low serum T levels markedly increases BMD in both the spine and the hip over 3 yr. The addition of F to T does not diminish increases in BMD but does decrease prostate growth and increases in PSA compared with treatment with either T alone or placebo. Given its beneficial effects on BMD, larger, long-term randomized studies of T therapy with and without inhibitors of 5 α -reductase should be conducted to better define the risks and benefits of T therapy and its impact on the risk of osteoporotic fractures in older men.

1. INTRODUCTION

This report is submitted by the team of Independent Observers (IO) from the World Anti-Doping Agency (WADA), which was present at the Tour de France 2003. The IO team was able to observe the anti-doping programme implemented by the various organisations working in cooperation during the Tour: The International Cycling Union (UCI), the French Ministry of Sport, the Amaury Sport Organisation (ASO), the French Council for the Prevention and Fight against Doping (CPLD) and the French National Drug Testing Laboratory (LNDD).

The team appointed by WADA to carry out this task comprised 3 members, all regarded as experts in their particular fields.

2. INITIAL PREPARATIONS AND MEETINGS

In the run up to the 2003 Tour, WADA circulated an agreement among the relevant parties in order to confirm that, in accordance with the mandate of the IO programme, the observers would have access to all the relevant documentation and would be able to observe the anti-doping control process implemented for the Tour de France at its various levels. In spite of a few initial problems associated with the legal constraints specific to the Code of Public Health in France hosting the Tour, it was possible to reach an agreement authorizing the WADA team to observe the following procedures:

- selection procedures;
- notification of the cyclists selected for the controls;
- analysis of samples at the LNDD;
- preparation of the controls;
- compiling of the appropriate forms after the controls;
- preparing the sample for dispatch to the laboratory;
- procedures in the event of a "B" sample.

In addition to this, the observers were able to enter the doping control station, provided that they were medical doctors and there was adequate room to accommodate the cyclist, the doctor taking the sample, the UCI delegate and possibly the accompanying person of the cyclist.

An anonymous copy of the doping control forms, as well as a copy of the analysis reports were also supplied to the observers.

Before the observers arrived in Paris, arrangements were made for several meetings to be held in order to ensure, on the one hand, that just as events were starting off, all the parties concerned would be informed of each other's role in the process, while also ensuring that there would be no problems from an organisational point of view.

Two important meetings were held during the first two days, on 1st and 2nd July, in Paris. During the first meeting between a representative from WADA and M. D. Baal, Deputy Director of the Tour, the entire logistics for the event, including accommodation, transportation, etc. were reviewed and coordinated. A car and driver were made available to the observers from the time they arrived in Paris.

A second meeting took place between representatives from the French Ministry of Sport, CPLD, UCI, ASO, LNDD and the WADA observers, which focused on this first contact being made and on explaining the WADA observers' mission, their objectives and role during a sporting event. All the steps involved in the anti-doping test process implemented during the Tour were described in detail and explained. Furthermore, an agreement was reached on guaranteeing anonymity with regard to the copies of reports sent to the observers.

It is important to note that during the meeting the CPLD expressed its opinion about the exchange of information with the observers relating to the doping control forms. It did not agree with the compromise offered by the French Ministry of Sport and consequently, the CPLD stated that it declined all responsibility in the event of any dispute.

During the meeting the President of the IO team emphasised that this type of mission is carried out based on a positive, constructive approach. These objectives can only be achieved with the cooperation of all the present parties based on a system of ongoing communication to help avoid any problems during the mission.

During this meeting, the President also gave all the relevant authorities copies of the documents guaranteeing confidentiality with regard to the information gathered as part of the mission and to the commitment to expose any personal conflict of interest.

On the evening of 4th July, the WADA observers were invited to attend the general reception for the teams being held at Paris City Hall. Race officials not only made the most of this occasion to inform the teams about the Tour de France's Code of Ethics, along with its regulations on behaviour and safety, but they also made the cyclists and their backup teams aware of the issue of doping¹. The anti-doping testing process was quickly explained and an appeal was made to the cyclists for maintaining the spirit of fair play.

RECOMMENDATIONS

It is essential that in future, agreements between the various parties are reached and signed well beforehand in order to guarantee the best possible organisation for all the parties concerned. The agreement was sent to the relevant parties on 16th May 2003 and it was only on 27th June, virtually just before the observers were due to arrive that agreement was successfully reached.

3. MEDICAL CHECK-UP

Before the start, all the cyclists underwent a medical check-up, including a blood test and a medical examination.

a. BLOOD TESTS

All 198 riders officially registered for the 2003 Tour de France underwent a blood test the day before the start of the race.

The samples were taken at the hotels where the teams were staying from 7.30 AM onwards. These tests were carried out under the responsibility of the UCI, which appointed several teams made up of a doctor to take the sample and two UCI commissioners.

¹ See pages 30-31 of this report for more details

Three samples were taken from each rider: an A sample and a B sample for evaluating the levels of haematocrit, haemoglobin and the percentage of reticulocytes and free plasma haemoglobin; a third sample for evaluating other biological parameters (transaminases, glucose, iron, transferrin, ferritin, cortisol, etc.).

The IO team members observed the procedures for taking the blood samples, compiling the forms and transporting the samples to a temporary laboratory located in a hotel. There were two different teams working in the laboratory. One was from the Lausanne Laboratory and the other from the Ghent Laboratory. Each team was made up of a Scientific Director and a Technician. The Swiss team used a Sysmex ® analyzer, while the Belgian team used a Coulter ACT 8 ®. The laboratory was also equipped with a centrifuge and a Hemocue® analyzer for measuring free plasma haemoglobin. This is the first occasion where the UCI has not only evaluated the usual parameters (haematocrit, haemoglobin and the percentage of reticulocytes), but also free plasma haemoglobin, which rises quite significantly when synthetic haemoglobin is administered.

When the analyses, which were carried out immediately as soon as the samples arrived, showed abnormal profiles (abnormal values or trends), the UCI questioned the rider (or his doctor) about the source of this abnormality, or let him know that he would have another test carried out during the race and that he would be classified as being suspect by the UCI Anti-doping Commission.

The UCI authorised the observers to attend all the health check procedures, but not when the results were being issued. The reason behind that being that the health checks were not part of the anti-doping process. Nevertheless, the observers do not share this view because on several occasions during the Tour, the UCI carried out tests in competition and out of competition based on suspect results from blood tests taken as part of the health checks.

This strategy paid off with a out-of-competition control during the Tour, which showed a positive result for erythropoietin (EPO).

Since this year, the UCI has been using a new protocol for identifying riders with an abnormal blood profile. If, for instance, a rider has a haematocrit value of 48% (below 50%), but if the average value of the four previous samples taken was 43%, the Anti-doping Commission will automatically make this rider provide a urine sample to be screened for EPO.

The two doctors included in the IO team were able to view the UCI's blood parameters database and listen to the explanations from Mario Zorzoli, the UCI doctor, about the strategy linked to the health checks.

Appendices I and II describe the procedure for the medical examination carried out to determine blood parameters and the protocol for measuring free plasma haemoglobin. Appendix III contains the letter sent to all the riders before the race containing some information about the blood tests.

The third blood sample was dispatched in refrigerated form to a laboratory in Switzerland for an evaluation of the other parameters, which would be passed on to the UCI doctors at a later stage.

All the technical and administrative procedures were carried out quickly, in a highly professional manner and with the excellent cooperation of all the riders.

During the health checks the commissioners requested health booklets from all the riders for them to photocopy. During the technical meeting on 4th July the UCI Medical Commission returned the health booklets and informed the team representatives of the results from the health checks.

One member of the IO team was also present at the health checks carried out on 9th July, where all the riders in the six teams were examined.

During the Tour the UCI carried out other health checks after the observers' departure, where all the riders with suspect results had to undergo a out-of-competition control or a control on the same day at the end of the stage in order to screen for erythropoietin.

The day before the first health check, the UCI held a meeting attended by the doctors involved in taking the samples and the laboratory managers to explain to them their duties and responsibilities and to issue the relevant documentation and equipment to them.

The observers would like to congratulate the UCI for implementing this strategy involving health checks, which is still at the moment and was in the past a very important measure for protecting the riders' health. The introduction of testing for abnormal biological profiles and the evaluation of free plasma haemoglobin demonstrate that the UCI strives to improve its health check procedures.

Based on the analysis of the individual assessments, it is possible to divide the riders into three categories:

- Those who will be banned from starting due to a haematocrit level above 50% and a haemoglobin level higher than 17 g/dl;
- Those with no biological abnormalities;
- Those who will be authorised to start but, due to a biological profile regarded as "suspect", will have to be included in the group of riders obliged to take a urine test to be screened for EPO at the end of the prologue.

RECOMMENDATIONS

- *During any future WADA observation mission, the UCI should supply the results from the health checks to the WADA team to prove the system's effectiveness (total, indisputable transparency).*
- *The UCI should provide a copy of the completed form with the sample codes for each rider.*
- *Samples should be transported in refrigerated form in a sealed case, along with an appropriately completed security document.*

b. MEDICAL EXAMINATION

On 3rd and 4th July all the riders underwent a medical examination organised by the medical team employed by the ASO led by Dr. Gérard Porte.

The medical team's aim was to make an initial contact with all the riders. It comprised six doctors and two nurses.

A medical record was completed for each cyclist, who underwent several observations and examinations: weight, height, spirometry, cardiopulmonary auscultation, blood pressure and ECG.

The technical procedure used for measuring weight and height was not appropriate, nor were the conditions ideal for cardiopulmonary auscultation (the rooms in the large hall of the Palais des Expositions did not have integrated ceilings and there was background noise. The cars following the Tour were also located nearby). The cyclists' privacy was not respected either. For instance, the ECGs were carried out in a large room with four beds and no curtains separating them from the ever-present media.

It is vital and necessary for contact to be made between the medical team in charge during the Tour de France and the cyclists and their doctors, but some basic principles of medical practice need to be observed.

RECOMMENDATIONS

- *The cyclists' privacy should be respected.*
- *Examinations and, in particular, recording the cyclists' medical history should be carried out in an atmosphere of peace and quiet in order to obtain as much information as possible from the cyclists.*
- *The procedures for measuring weight and height should comply with normal technical procedures.*
- *It is vital that the cyclist's medical record is supplied and that the team doctor is interviewed.*
- *Closer cooperation with the UCI medical team and the issuing the results of the blood analyses carried out in Switzerland will definitely benefit this large medical structure put in place for the Tour de France.*

4. OUT-OF-COMPETITION TESTING BEFORE THE START

The day before the start, the UCI decided to control at random two cyclists who had "suspect" biological profiles.

On the morning of the prologue another cyclist was also tested. The three riders' urine samples were screened for erythropoietin.

The IO team was present at one of the tests carried out by a team made up of the Anti-doping Inspector and a doctor from the UCI. The test was carried out in accordance with the technical and administrative procedures set out by the UCI's Anti-doping regulations. The three samples were transported to the laboratory along with the samples taken after the prologue, which was 34 hours after the first out-of-competition sample was taken.

The observers did not see the conditions for storing and ensuring the security of these three samples taken during a random test between the time they were taken and their arrival at the venue for the anti-doping test during the prologue.

The observers agree with the UCI's strategy of testing at random cyclists with "suspect" results from the health checks.

RECOMMENDATIONS

The observers recommend that the samples are transported immediately to the laboratory after being taken and not 34 hours afterwards.

5. IN-COMPETITION TESTING

The French Ministry of Sport, the UCI and ASO shared responsibility for in-competition testing. The Ministry of Sport appointed a doctor responsible for all the samples taken.

The selection of the athletes took place every day one hour before the finish in the UCI Anti-doping Inspector's car in the presence and with the cooperation of the doctor appointed by the Ministry of Sport.

In accordance with UCI Anti-doping regulations, at each stage, the wearer of the yellow jersey and the stage winner were automatically selected to take an anti-doping test. During several stages the Anti-doping Inspector received a message from the President of the UCI Anti-doping Commission instructing him to select directly a few riders with "suspect" profiles from the blood tests.

Usually three other riders were then selected randomly to give a total of six or seven riders to be tested and two reserve riders. Half an hour before the finish, the anti-doping inspector would give the President of the board of commissioners the jersey numbers of the riders selected for testing, as well as those of the reserve riders. This information would then be passed on by the President via the Tour radio (accessible to Tour officials) twenty minutes before the finish. The names and numbers of the riders were then displayed at the entrance to the anti-doping control station.

During the time-trial stages lots would be drawn before the first rider set off and notice would be given by a UCI commissioner five minutes before each selected rider set off. After the finish the rider had an hour to report to the doping control station without ever being accompanied.

The Ministry of Sport doctor took the urine samples in two caravans made available by the ASO, one of which was used as a waiting room. The doping control station was at least 50 metres from the finish line and the press rooms. It was surrounded by barriers with a door opening onto the course. There was always a security guard from the organisation at the door.

The Berlinger ® system was used to take the samples and the forms from the Ministry of Sport were used as report templates.

Once all the tests were carried out, the doctor taking the samples and the Medical Inspector would put all the in-competition samples and the out-of-competition samples from the same day in a case containing dry ice required for transporting the samples at minus 20 degrees Centigrade.

The case was immediately brought to the heliport or airport where a helicopter or plane chartered by the organisation was waiting each evening to take the case and the samples to Bourget airport in Paris where they were handled by a private carrier. This carrier brought the samples between 0900 and 1000 the following day to the Châtenay-Malabry anti-doping laboratory.

The IO team observed the system for selecting the riders, the notification system, the procedures for taking the samples and the team also monitored the riders after the finish until they reported to the testing area during the prologue and the first four stages. The observers also monitored the case containing the samples from the doping control station right to the premises of the company assigned with their transportation during the day of the prologue. At the end of anti-doping testing after the third stage, the observers monitored how the case was brought to the heliport.

During the Tour, 132 urine samples were taken in-competition (6 samples for fifteen stages and 7 samples for 6 stages).

Most of the procedures followed during the in-competition tests complied with the UCI Anti-doping regulations and/or WADA International Standard for Testing. However, the observers identified a few discrepancies with regard either to the UCI Anti-doping regulations or the International Standard for Testing.

a. SELECTION PROCESS

When the riders were selected during the second stage, one of those selected by the President of the UCI Anti-doping Commission was not notified at the finish due to an error when noting the numbers of the riders selected. During the selection process at the third stage, the inspector had made a mistake noting the figures in the jersey number of the selected rider. Because of the confusion from the previous day when a rider was omitted, the latter was selected automatically for testing that day by the President of the UCI Anti-doping Commission.

b. NOTIFICATION

During the prologue the cyclists were notified five minutes before the start. This meant that the cyclists who were not notified then still had the opportunity to take a stimulant before the start of the race, as they were certain not to be tested (unless they won!). Of the six cyclists tested during the prologue only one reported for testing more than 60 minutes after notification, without any comment from the inspector. The Anti-doping Inspector informed some of the athletes and managers that they had 60 minutes to report for testing.

During the road-racing stages notification was given via the Tour-radio 20 minutes before the end of the race. This meant that the riders who were not selected again had an opportunity to take a fast-acting stimulant because they knew for certain they would not be tested (unless they won!).

c. ESCORTS

There were no escorts. The cyclists sometimes took over 20 minutes to get changed in their team trucks. Some kind of manipulation could have taken place.

d. TESTING AREA

There was no sign available to indicate where the anti-doping control station was. In addition, the testing area's location was not indicated in the route guide. The anti-doping caravan (waiting room and area where samples were taken) and the relevant doctor's car had a "Contrôle Médical" (Medical Test) sign rather than any mention of anti-doping.

In one instance, a cyclist and his doctor were meant to report for the anti-doping test, but could not find the venue due to the lack of signs.

The premises where the tests were carried out were far too small. There was also no system for recording when people came and left the area.

Every day there were unauthorised people in the anti-doping control and waiting areas, such as chauffeurs, mobile-home drivers and sometimes even members of the media.

With a UCI doctor's authorisation, a television crew was able to enter the restricted area and film the doping control station with only a WADA observer present. Afterwards, the TV crew remained in the restricted area around the caravan and filmed cyclists leaving the testing area, as well as the inside of the testing and waiting areas when a cyclist was there. Finally, the TV crew filmed a close-up of the procedure for filling and closing the dry ice container.

e. PROCEDURES FOR TAKING SAMPLES

Cyclists did not receive at any time an explanation of what the anti-doping test procedures involved.

Often the doctor taking the sample carried out himself the process for filling the samples without requesting the cyclist's authorisation or recording this action on the test form. Given the numerous (7) copies of the report which had to be made, the last copy, intended for the laboratory, was on several occasions virtually illegible.

The cyclist's privacy was not respected during micturition. This was carried out with the Anti-doping Inspector present, while the small bathroom was used to store the equipment and samples after they had been taken.

On at least one occasion, the doctor taking the sample left the caravan when the cyclist was trying to urinate. The Anti-doping Inspector was not able to observe the cyclist from where he was, although this was not part of his function.

The doctor taking the samples never measured their density and pH.

According to the doctor taking the samples, pH and density are not measured because of a directive from the LNDD (French National Drug Testing Laboratory) issued two years ago stating that this measure was not necessary.

The Independent Observers, however, questioned the Ministry of Sport on this matter, which informed them that neither UCI regulations nor French law made this measure compulsory, even if there was a relevant box for this purpose on the form and that it was stipulated by the Olympic Movement Anti-doping Code.

Whenever there was a sample containing an insufficient quantity of urine the doctor taking the samples never used the Berlinger® system intended for this purpose (with blue caps). A cyclist held his open sample in his hand, at one moment he was even left all alone in the doping control station. Despite this, the doping control form provides a section for indicating the number of the intermediate seals, which was therefore never used.

The doctor taking the samples always observed the 75 ml limit. Sometimes, when analysing EPO, a larger quantity of urine is required. To obtain this it would have been preferable to pour more urine into the bottles even if there was already a sufficient quantity of urine.

On several occasions the doctor took more than 75 ml urine, the quantity taken was noted in the report. He then filled bottle A and bottle B up to the label and the rest of the urine was poured down the toilet.

The doctor taking the samples noted all the drugs featuring in the rider's health booklet on the form and asked him to state all the drugs he had recently taken. He did not ask him to state the nutritional supplements he had taken. The doctor often did not ask the rider if he had any comments to make about the procedure.

After a cyclist was tested the samples were not kept in a safe, refrigerated place. The Berlinger® set with the sample was placed on the ground in the small bathroom in the caravan, which was not used for micturition.

During the prologue controls, the three samples from the random control taken in the morning were kept refrigerated in the carry case, which was not sealed and was located outside the caravan near the entrance.

In one case, the cyclist's copy of the doping control form was detached before the Cycling Director could sign the form. He signed it afterwards but the cyclist's copy did not have his signature on it. The various copies were put in envelopes and sent by normal post to the relevant authorities. The copies were therefore not kept in sealed envelopes.

Once the in-competition tests were complete, the container of dry ice was emptied in the street in full public view, with the samples placed on the ground nearby.

Then all the samples were placed in the container again and the driver of the doctors' car put the dry ice back in the container using plastic bags to protect his hands.

The actual container was not sealed. The unsealed envelope containing the copies of the laboratory reports and the sample security form were placed under the lid of the container, which did not close properly. This envelope was therefore in full public view and easily accessible.

f. TRANSPORT

There was no transport form (security form for the case).

After the prologue, the doctor taking the samples and the Anti-doping Inspector took the container to their hotel. Immediately when they arrived, the container was given to an employee from Dynaposte® (who was not requested for proof of identity). This company did not supply the doctor taking the samples with a transport form. This meant that the doctor had no proof that the samples had actually been delivered. Dynaposte® transported the samples to a post office where they were kept in air-conditioned premises. The post office's security system consisted of an alarm and access code. Dynaposte® does not have a quality control system. The samples were scheduled to be dispatched to the laboratory at 9 AM the following morning.

RECOMMENDATIONS

The following measures are recommended by the IO team as a means of improving the anti-doping test procedures at the Tour de France:

- The procedures for selecting the riders should be carried out in an atmosphere of peace and quiet to prevent any mistakes being made.*
- UCI Anti-doping regulations should describe precisely when the riders should be notified during the time-trial and road-racing stages. The form described in the UCI Anti-doping regulations should only be used for notification after the finish, preferably in the mixed area or alternatively, beside the relevant team trucks.
The Observers believe that this system can be totally practicable, even during a major competition like the Tour de France.*
- Once notification has been given, an escort trained specially for this purpose should accompany the rider until he arrives at the anti-doping control station, as described in the UCI Anti-doping regulations (Article 53) and in accordance with Article 5.4 of the International Standard for Testing.*
- The time the rider has to report for testing specified in the UCI Anti-doping regulations (Article 54 – 30 minutes or 50 minutes, if he has to attend a press conference) should be observed.*
- The testing area should be clearly signposted from the finish line (Article 38 of the UCI Anti-doping regulations).*

- *The testing area should comply with UCI recommendations (Article 39), especially with regard to its dimensions, guaranteeing riders' privacy during the test, as well as with Article 6.3 of the International Standard for Testing.*
- *The person appointed to guard the entrance to control station should have a system for recording who enters and leaves the area. The press, organisation drivers, mobile home drivers and other persons not involved in the anti-doping test process should not enter the testing area (Article 40 of the UCI Anti-doping regulations).*
- *The doctor taking the samples should explain the procedures to the riders, give them the opportunity to ask questions and take all the samples in a calm environment and in accordance with Article 47 of the UCI Anti-doping regulations and the procedures specified in WADA's International Standard for Testing (Article 7.0).*
- *The doctor taking the samples must ask riders which nutritional supplements they have taken, as this information could help with the interpretation of a positive analysis report and the decision on what kind of sanction to impose (Article 10.5 of WADA's World Anti-doping Code).*
- *The french doping control form should be amended so that there are fewer copies or that the copy to be sent to the Laboratory is the third or fourth sheet so that it is more legible. The IO team does not understand why one copy has to be supplied to the National Federation and a second to the International Federation.*
If it is an international competition the copy should be given to the International Federation and if it is national it should be given to the National Federation. The IO team wonders why a copy has to be supplied to the French Ministry of Sport if the French Council for the Prevention and Fight against Doping already receives one.
- *The doctor taking the samples should pour all the urine collected into bottles A and B because it is sometimes the case that the laboratory needs a large amount of urine to be able to confirm a quantifiable substance or detect erythropoietin.*
- *The samples should be kept refrigerated in a secure place after they have been taken.*

- *The doctor taking the samples and the UCI Anti-doping Inspector should place the copies of the report in the envelopes intended for the various recipients after the last sample has been taken and close them using the security seals (Article 66 of the UCI anti-doping regulations).*
- *The doctor taking the samples should draft a report after each doping control session. A single report at the end of the Tour mission would not allow for corrective measures to be taken if there were irregularities in one of the controls during the actual Tour.*
- *The samples and envelope containing the reports to be sent to the laboratory should be placed in a case, which should be sealed by the doctor taking the samples and the Anti-doping Inspector.*
- *The doctor taking the samples or the Anti-doping Inspector should complete a security document for the case (in accordance with Article 9.3.2. of the International Standard for Testing), specifying the date and time at which the case was sealed and the security seal number. The integrity of each person who will carry the case should be guaranteed and a new entry must be made in the security document when the case is received.*
- *The Tour's organisation should choose a company with a quality assurance system to transport the case.*
- *The samples should be transported in a case refrigerated at a temperature between 0°C and 10°C while in transit.*
Transporting the samples at -20°C is secure but it slows down the procedures for preparing the samples in the laboratory as they have to wait until the samples have thawed once they have arrived.

6. OUT-OF-COMPETITION TESTING DURING THE TOUR

A total of seven out-of-competition controls were carried out during the Tour de France (one on 7th July, two on the first rest day, one on 18th July and three on the second rest day). The doctor from the Ministry of Sport taking the samples carried out the controls in cooperation with the UCI Medical Inspector.

The President of the UCI Anti-doping Commission decided on the riders to be selected and the laboratory screened all the samples taken for erythropoietin.

One of the WADA observers observed one of the controls carried out at 7 AM on 7th July. It was carried out at the rider's hotel. The only remarks to be made relate on one hand to the time the rider took to report for the control – 23 minutes – after being notified by one of the team managers without being accompanied by the UCI Medical Inspector and on the other hand to the system for transporting the samples. After taking the samples, the doctor carried them in a small bag.

RECOMMENDATIONS

- *The UCI and French Ministry of Sport should carry out more controls, especially to monitor riders with "suspect" blood profiles, instead of monitoring them by selecting these riders for in-competition controls. Post-competition proteinuria can make it more difficult to interpret the results from the procedure for detecting erythropoietin in the laboratory.*
- *The UCI Medical Inspector should accompany the team manager from the time of their meeting until the rider is notified.*
- *The samples should be transported and stored in a refrigerated case, closed with a security seal until the time it is finally transported to the laboratory.*

7. LABORATORY

The analyses of all the samples taken for anti-doping testing, in competition and out of competition during the Tour de France, were carried out by the French National Drug Testing Laboratory (LNDD) in Châtenay-Malabry.

The LNDD is a national public, administrative institute, which operates under the responsibility of the Ministry of Sport.

This laboratory carries out analyses under the terms of Article L.3632-2 of the French Public Health Code and is responsible for managing and sending the equipment required to take the samples, as specified in the article of the Decree of 11th January 2001 mentioned above. Another of the LNDD's tasks is to carry out research in the area of doping prevention.

The laboratory has evolved historically as part of the institutional framework represented by national and international sporting bodies (sports federations, International Olympic Committee and World Anti-Doping Agency) and administrative bodies in the form of the Ministry of Sport and more recently (1999) the Council for the Prevention and Fight against Doping (CLPD).

In view of this, the laboratory's activities meet the requirements of national regulations and those of the sporting bodies.

At the moment, the LNDD is the only establishment in France approved by the IOC and WADA for carrying out analyses of anti-doping controls. In order to maintain the quality level of the service provided, the remuneration of the staff involved in carrying out the analyses does not depend on the number of samples processed nor on the results of these analyses. The LNDD is situated in the Châtenay-Malabry centre for popular education and sport (CREPS). It is made up of three technical departments, a paratechnical department, a quality assurance department, as well as a general secretariat. It has a current capacity for processing around 9,000 samples annually, based on 800 (between 700 and 900) per month over 11 months, taking into account a period of one month to deliver the results from the time the samples are received at the laboratory.

The Laboratory's management team is made up of the Director of the Laboratory, Prof. Jacques de Ceaurriz and a General Secretary. The Director is the laboratory's technical manager.

The LNDD has a staff of 40 comprising:

- 1 Director
- 1 General Secretary
- 3 Heads of department
- 1 Quality Assurance manager
- 23 technicians and 3 para-technical staff

- 8 administrators.

The laboratory has three technical departments. The various heads of department are also the technical managers for their respective departments:

- Department of GC chemical testing. This testing department is responsible for carrying out conventional analyses using gas chromatography, with or without mass spectrometry.
- Department for analytical research and development and LC chemical testing. Its function is to develop new analytical methods for identifying new doping products, as well as to improve already existing ones.
- Department for biological research and development and immunochemical testing. Its function is to develop new biological analytical methods for identifying new doping products, as well as to improve already existing ones. This department is responsible for the technical procedures of erythropoietin screening.

The laboratory's quality control system has had general accreditation from COFRAC (French Committee for Accreditation) in Medical Biology (no. 1-1174) since 1st June 2001.

The LNDD currently has the following equipment:

11 units – GC/MS

3 units – GC/MS-MS

2 units – (LC/MS)

2 units – system for analysing luminescence with dark room and optical system

1 unit – (LC/MS-MS)

An observer from the IO team visited the LNDD on the morning of 10th July. The observer was very warmly welcomed by the Director and quality assurance manager. He was able to visit the laboratory facilities, which are currently under renovation. These facilities are quite extensive offering an ideal separation between all the departments and sections. For instance, each technical department has a screening section, confirmation section and research section.

The observer witnessed the reception of the samples taken during the 4th stage, which arrived at the laboratory via Dynaposte® at around 10 AM.

The procedure for receiving the samples was carried out in a highly professional manner, in accordance with the laboratory's quality system and WADA's International Laboratory Standards. The samples were frozen at the time of their reception.

The observer was able to look at some of the laboratory's quality documents. The quality control system is well structured and implemented in a very active and highly professional manner.

The IO team concluded that the analysis reports described the methods used for screening and confirmation, but that these reports did not mention the technical procedure codes used.

The IO team also concluded that there were a few weaknesses concerning the security system. For example, a door leading outside remained open while the samples were being received; the WADA observer was not asked for identification at the entrance to the laboratory and his presence was not recorded.

The laboratory sign at the entrance on avenue Roger Salerno was not very visible, which made it difficult for any visitor trying to locate it.

During the Tour de France the Laboratory made small changes to the way in which it organised its daily activities. The samples from the Tour de France were processed as a priority and working hours were extended slightly, but the laboratory was not open at night or during the weekend.

Outside normal working hours and during the weekend, there was nobody at the laboratory, not even a security guard. The laboratory does, however, have a double security system:

- centrally controlled anti-burglary shutters on all the windows
- an alarm linked to a remote monitoring and response centre (at the Director or General Secretary's request).

While the WADA IO team was present at the Tour, following a telephone call between 3 and 4 PM, the laboratory sent the analysis reports by fax, ensuring anonymity was preserved, to the President of the IO team.

After the IO team's departure the Laboratory sent the analysis reports every day via the IO team President's confidential fax number in Lisbon.

The analysis reports were sent to the UCI Anti-doping Commission and the President of the French Council for the Prevention and Fight against Doping (CPLD) and for information, to the President of the International Olympic Committee's Medical Commission and to the person dealing with these matters at the French Cycling Federation.

During the Tour de France the LNDD processed a total of 142 samples (132 taken in-competition and 10 out-of-competition). In 2002, 138 samples were taken and 170 samples in 2001.

The in-competition samples taken during the prologue, 2nd, 4th, 6th, 7th, 8th, 9th, 12th, 13th, 14th, 15th, 16th, 18th and 19th stages and all the out-of-competition samples were screened for erythropoietin and hydroxyethyl starch (HES).

This type of screening was carried out on a total of 100 samples (70.4% of all the samples taken during the Tour), which marks an increase compared with the last few years (82 samples in 2002 and 72 in 2001).

All the samples were also screened for glucocorticosteroids.

The timetable for taking samples was drawn up by the French Ministry of Sport and the LNDD in cooperation with the UCI Anti-doping Commission. Either the Ministry or the UCI gave the laboratory the order to carry out the EPO analyses on the samples.

During the Tour de France the time taken for the results to be issued to the WADA IO team was on average around 66 and 72 hours after receipt of the samples at the laboratory for normal and EPO screening procedures respectively.

The time for issuing the results for normal procedures was around 100 hours for samples taken during the 12th and 14th stages. It must be pointed out that samples arrived at the laboratory every day, at least 14 hours after the in-competition tests had been completed.

Tables 1 and 2 show all the reports indicating the presence of doping agents.

Table 1

Reports indicating the presence of doping agents other than erythropoietin

| Substances | Number of samples | Comments on concentrations |
|-------------------------|--------------------------|--|
| Triamcinolone acetonide | 28 | Median – 6.0 ng / ml Variation – 1.0 ng / ml – 19 ng / ml |
| Betamethasone | 6 | Median – 26 ng / ml Variation – 1 ng / ml -37 ng / ml |
| Salbutamol | 6 | Median – 143 ng / ml Variation – 87 ng / ml -449 ng / ml |
| Dexamethasone | 3 | Median – 10 ng / ml Variation – 8 ng / ml -15 ng / ml |
| Caffeine | 1 | 10.7 µg / ml |
| Terbutaline | 1 | |
| Lidocaine | 1 | |
| Total: | 46 | |

Table 2

Reports indicating the presence of recombinant erythropoietin or with anomalies

| Classification | Number of samples | Comments |
|---|--------------------------|---|
| Presence of recombinant erythropoietin | 1 | |
| Undetectable recombinant erythropoietin | 15 | Camera intensity below 10,000 LAU |
| Unclassifiable recombinant erythropoietin | 4 | Electrophoretic migration between 48% and 65%, between 65% and 85% for NESP and for epoietin alfa and beta respectively |
| Total: | 20 | |

Looking at Table 2, it should be pointed out that 20% of the test results for the samples analysed for EPO had anomalies and that the only positive case was recorded in a sample taken out-of-competition.

The IO team has to emphasise the quality of the LNDD in terms of management, quality control system, facilities, staff and equipment. It would like to thank the laboratory's managers for their due cooperation throughout the whole of the Tour de France.

RECOMMENDATIONS

The IO team would like to make a few constructive recommendations with a view to optimize the services provided by the LNDD during the Tour de France:

- *The laboratory should reduce the time taken to issue results during the Tour de France. In a competition organised in stages like the Tour de France, a delay in announcing a positive result can allow a rider who has taken drugs to distort the competition results for a few days.*

To achieve this aim, the IO team recommends that the laboratory increase its working hours, by operating extra hours at night and during the weekend and that samples are transported at between 0°C and 10°C to facilitate the start of the technical procedures carried out in the laboratory.

- *The laboratory should have a system for receiving the samples 24 hours a day, which would facilitate the security system protecting the samples and the start of the technical procedures.*
- *The laboratory's security system should be reviewed to eliminate a few weak spots.*
- *The laboratory should enter in the report the codes for the technical procedures used in the analyses to make the information clearer for its customers.*

8. HANDLING THE RESULTS

The IO team would like to say at this point that, in addition to the analysis reports from the LNDD, it also received copies of the reports with the concealed identities of the riders from the doctor taking the samples, because the French law does not allow them to be disclosed.

The results were handled during the Tour de France by the UCI (UCI Anti-doping control regulations) and by the French Council for the Prevention and Fight against Doping (CPLD) (French Public Health Code – Article L 3612-1).

a. WHILE THE OBSERVERS WERE PRESENT

During this period the IO team received a copy of the reports either from the doctor taking the samples or the UCI Medical Inspector the day after each test, in competition or out of competition. The observers have nothing to report during this period.

b. AFTER THE OBSERVERS' DEPARTURE

During this period the President of the IO team received copies of the reports at his confidential fax number in Lisbon or by post.

On 25th July at 1440 (Paris time), the President of the IO team received a fax of analysis report no. 117/07-EPO, which confirmed the presence of recombinant erythropoietin in a sample taken on 18th July during an out-of-competition control. Twenty minutes later the President of the IO team received a telephone call from the President of the UCI Anti-doping Commission, who provided the same information and said that the UCI Medical Inspector was going to inform the rider and his cycling manager after the final stage of the day.

On 1st August the President of the IO team received the report on the B sample analysis carried out at UCI's request on 28th July, which confirmed the presence of recombinant erythropoietin.

On 4th August the President of the IO team requested additional information from the President of the UCI Anti-doping Commission concerning the disciplinary procedures applied in the event of a positive test, as well as information about the existence of other disciplinary procedures concerning positive results obtained by the LNDD, relating to samples taken during the Tour de France (copy of fax in Appendix IV).

On 6th and 7th August the President of the IO team received faxes (in Appendices V and VI) from the President of the UCI Anti-doping Commission informing him that the positive result case was handled in accordance with Articles 174 to 183 of the UCI Anti-doping regulations.

The UCI received the result of the B sample analysis after the final day of the Tour de France and for this reason, it was not possible to apply the principles described in Article 183 of the UCI Anti-doping regulations i.e. to exclude the rider from the race. The case was handed over to the rider's national federation, in accordance with Article 113 of the UCI Anti-doping regulations for it to apply disciplinary procedures, which must be completed within one month of the time limit set for the dispatch of the summons.

In a fax of 6th August the President of the Anti-doping Commission advised the observers that all the other positive cases were examined by the UCI Anti-doping commission, which decided that all these cases were justified on medical grounds. In the case of treatments taken during the Tour de France, all these treatments had been prescribed with the cooperation of the UCI's medical experts and were entered in the riders' health booklets.

The IO team reviewed the drugs declared in the reports and noted that in 71.8% of the samples taken the riders had declared that they had taken a drug. In 60.6% of the samples taken, glucocorticosteroids were administered and in 27.5% of cases beta-2-agonists were used.

The IO team confirmed that, in spite of the information from the UCI Anti-doping Commission about the existence of justified medical grounds in every case where there was a positive result for glucocorticosteroids, the timescales between the date the sample was taken and the date entered in the health booklet when the substance was administered were extremely large.

The IO team calculated these differences in twenty of the twenty-eight positive reports with triamcinolone acetonide, which was 37 days on average, with a variation between 8 and 57 days. In five cases the difference was more than 45 days. The IO team could find no reliable scientific data which could support a urinary excretion time of this duration.

On two occasions the IO team did not find that there was any medical justification concerning the cases showing a positive result for glucocorticosteroids:

- one positive result with triamcinolone acetonide with a medical declaration specifying Betamethasone by infiltration;
- one positive result with Betamethasone (30 ng/ml) with a medical declaration specifying cutaneous application of Betamethasone, the last occasion being 39 days before the test.

On the 18th August the President of the IO team requested additional information from the General Secretary of the CPLD concerning the disciplinary procedures applied with regard to the positive results received from the LNDD, relating to the samples taken during the Tour de France (copy of fax in Appendix VII).

On the same day the President of the IO team received a fax from the General Secretary of the CPLD (in Appendix VIII), informing him that, apart from the cases involving EPO, where proceedings were already under way, the President of the CPLD sent an initial letter to several riders to ensure that a "proof of a medical prescription based on justified therapeutic grounds" is sent to the CPLD.

RECOMMENDATIONS

The IO team recommends the following measures for improving the system for handling results in the Tour de France and other cycling competitions:

- *Results should be handled by an Anti-doping Commission with representatives from the UCI Anti-doping Commission and the CPLD to avoid any conflicts. A single code of regulations should be adopted, in accordance with WADA's World Anti-doping Code.*

- *The UCI should adapt its anti-doping regulations to allow temporary suspension after the result of the B sample analysis has been notified and in accordance with the guidelines applicable to temporary suspensions under the World Anti-doping Code (Article 7.5).*

Any rider who has obtained a positive result from the test carried out during the Tour de France may continue to participate in competitions until the final decision is made by his national federation, which has one or two months (if the national federation has a disciplinary appeal body) to complete the disciplinary procedures.

Until the final decision is made, the rider can help other riders in competitions organised in stages to achieve victories or a good position in the classification. Article 184a of the UCI Anti-doping regulations does not cover every case where temporary suspension proves to be necessary in order to ensure sporting equality.

- *It is necessary to carry out studies into the urinary excretion of glucocorticosteroids following administration of these products by inhalation, local injection, intra-articular injection or other forms of local application to verify the detection time for these substances in urine. We also recommend carrying out studies concerning the metabolism of cortisol in riders in order to detect a temporary or permanent inhibition of its production.*
- *The UCI Anti-doping Commission should be more careful in its analysis of substances and the dates entered in the health booklet when verifying the existence of justified medical grounds if, for instance, the Laboratory has detected a glucocorticosteroid, as specified in point 3 of Article 64 of the UCI's Anti-doping regulations.*

9. INFORMING AND EDUCATING ATHLETES

The day before the Tour de France started, the ASO organised a session to raise the riders' awareness with regards to doping issues in the reception room at the Paris City Hall. This session was attended by Patrice Clerc (President of the ASO), Jean-Marie Leblanc (Director of the Tour de France), Daniel Baal (Deputy Director of the Tour), Jean-François Pescheux (Competition Director), all the teams and their coaches and the members of the WADA IO team.

The organisers of the Tour, in particular, Jean-Marie Leblanc and Daniel Baal spoke in very clear and firm terms about observing the Tour de France's Code of Ethics and they reminded the riders that zero tolerance was applied in this competition.

Daniel Baal gave some explanations about the anti-doping controls which were to be carried out during the Tour and reminded the riders that the UCI would introduce for the first time during the Tour an analysis for free plasma haemoglobin with a view to detecting any possible use of synthetic haemoglobin. He announced that all the riders would receive the same leaflet as in 2002 entitled "Dopage et Cyclisme - ce que vous devez savoir" (Doping and Cycling - what you need to know), which contained very important and useful information for the riders (in Appendix IX).

Daniel Baal stressed the importance of the Tour de France's Code of Ethics (in Appendix X), which appears in the regulations and in the Tour guide book and was signed by all the teams.

This commitment was included both in the Agreement between the ASO and the International Association of Professional Cycling Groups (AIGCP) and in the Agreement signed with each team before the Tour started.

10. UCI MEDICAL COMMISSION

For the third time the UCI appointed a medical commission for the Tour comprising nine doctors. Based on a rota system, two of them were present at all times during the Tour. This commission's task was to observe, advise on and authorise the administration of drugs, especially those subject to restrictions.

The observers requested from the UCI to be informed of the Medical Commission's activities while they were present at the Tour. However, the observers never received any information about any requests made by any team doctor or rider to the Medical Commission.

The observers want to congratulate the UCI for setting up the Medical Commission.

11. MISCELLANEOUS

The French government has set up a system for importing drugs similar to the system introduced during the 2002 Tour.

This involves, in particular, recommendations about importing drugs, with an emphasis on the importance of professional team doctors having two medicine kits (an emergency kit containing possible doping substances and a backup kit without any doping substances).

It is also recommended that a list is kept up to date of all the drugs contained in the two kits being taken out and put back and that these documents can be shown, particularly during custom controls. The CPLD sent the ASO a document summarising these procedures with the reminder that doctors from foreign teams must declare the activities they intend to carry out when in France during the Tour de France. The observers congratulate the French government for this initiative.

The observers also have to congratulate the ASO for its reaction concerning the doping problematic and for implementing during the last few years measures capable of making a significant contribution to the fight against doping during the Tour de France. These include:

- Changes to the course so that fewer kilometres are covered in total and in the time-trial stages and easier stages with fewer hills.
- Ensuring that there are always two days' rest during the Tour with easier transfers.
- Producing a guide for hoteliers offering advice on the cyclists' food requirements and on measures for ensuring the riders get sufficient rest.

12. CONCLUSIONS

The Tour de France is one of the most important sporting events in the world, with huge media coverage and a considerable financial impact.

This is why the positive and negative aspects of this competition will attract so much media attention and therefore, may have major repercussions from an educational point of view.

The scandal during the 1998 Tour de France brought many changes in the fight against doping in almost every sport and in the world of cycling, in particular.

The changes made are moving in the right direction, based on closer cooperation between the responsible bodies (French Ministry of Sport, CPLD, UCI and the Tour de France's organisation) in developing a strategy to combat doping during the Tour de France. The meeting held before the Tour started, between the responsible bodies and WADA, is a good example to support the statement we have made. Accepting an Independent Observer team from WADA is another example of this positive development.

The anti-doping control system developed during the 2003 Tour de France involved considerable sums of money and sometimes was even excessively demanding (e.g. transporting the case containing the samples by aeroplane). It had weaknesses too, though, which may be highly significant in the pursuit of the ultimate goal – to protect the riders' health and retain the true spirit of sportsmanship, especially for the riders who do not use banned substances or methods.

The observers have no doubts at all about the good intentions of all those people involved in planning and implementing the system, but these small weaknesses may help possible cheaters to get round the system or find solutions they can use to defend their actions.

Procedures for taking samples might well be carried out under ideal conditions, but if there are riders who know for sure that they will not be tested twenty minutes before the finish line or even before they have started (time-trial stages) and have the opportunity to perform some kind of physical manipulation before they reach the doping control station, the system cannot guarantee sporting equality.

In spite of some weaknesses in the anti-doping control system, the observers would like to stress that there were strong, positive points to come out of the 2003 Tour de France:

- The firm tone adopted in the speech made by those responsible for organising the Tour de France about observing the Code of Ethics and the fight against doping.
- The soundness of the UCI's health check system and the important role this system plays in the fight against doping in cycling.
- The strategy developed by France in its fight against doping, especially in the area of legislation and through creating the CPLD, providing a high-quality anti-doping control laboratory and implementing measures to prevent trafficking of doping substances.

Closer cooperation between the bodies responsible for anti-doping controls during the Tour de France and the implementation of WADA's World Anti-doping Code and International Standards will be sufficient to guarantee an ideal system. However, all the measures implemented may not be enough if all the partners involved do not assume their responsibilities, especially with regard to protecting the riders' physiological limits. Furthermore, it is important to note that from now on, the observers will only carry out their mission if they have access to all the required documentation.

13. ACKNOWLEDGEMENTS

The observers would like to thank very sincerely all those who contributed to the success of this mission, in particular, the UCI, French Ministry of Sport, the ASO, CPLD and LNDD.

The President of the team would like to express his sincere gratitude to all the members of the IO team who were present during the 2003 Tour de France, where they demonstrated a high level of competence and availability.

15. APPENDICES

Appendix 1: Procedure for determining blood parameters (UCI)

Juillet 03

Procédure de l'examen médical pour la détermination des paramètres sanguins

0. Conditions générales

Le laboratoire accrédité par l'UCI est l'Institut Indépendant qui assume la responsabilité opérationnelle scientifique et médicale globale de la récolte des échantillons sanguins et des paramètres biochimiques nécessaires à l'établissement de valeurs fiables de l'hématocrite.

Le responsable médical du programme est le Professeur Patrice Mangin.

Pour chaque examen l'UCI désigne **un ou plusieurs Inspecteurs Médicaux**.

La procédure se déroule dans un local adapté qui peut être une chambre d'hôtel. Si possible dans l'hôtel où **sont logés les coureurs, pour les prises de sang. L'appareil de mesure est installé dans un endroit pratique pour la remise des résultats.**

1. La prise de sang doit avoir lieu avant tout effort physique et de préférence avant le petit déjeuner.

A cette fin, l'Inspecteur Médical de l'UCI transmet personnellement le formulaire "Notification au coureur" au Directeur Sportif ou au Chef d'Equipe, à défaut au coureur (dans un délai raisonnable).

2. Le coureur désigné doit se présenter

- dans le délai mentionné sur la notification;
- au médecin de l'Institut Indépendant, dans la chambre mentionnée sur la notification.

Il est obligé de déposer sa licence auprès de l'Inspecteur Médical.

3. Le laboratoire désigné s'engage à assurer les prises de sang veineux chez les cyclistes qui lui sont désignés par l'UCI dans les règles de l'art et à effectuer les analyses dans les délais requis.

A cette fin, **le laboratoire** met à disposition l'équipe médicale scientifique et technique nécessaire; notamment pour la prise de sang, un médecin diplômé, familier des problèmes du sport. **Le laboratoire garantit l'expérience du médecin quant à l'exécution de prises de sang successives.**

Le matériel du prélèvement est fourni par **le laboratoire**.

Les tubes sont rendus anonymes au moment du prélèvement.

NB. Sur demande du coureur, la prise de sang peut également être pratiquée par le médecin du G.S., à la condition *sine qua non* qu'il se conforme au protocole établi. La

Procédure de l'examen médical pour la détermination des paramètres sanguins

présence de l'Inspecteur Médical est obligatoire. A défaut ou si l'échantillon de sang n'a pas été prélevé dès le 1^{er} essai, la ponction est effectuée par le médecin de l'Institut.

4. Après les prises de sang, l'équipe **du laboratoire** effectue les analyses requises.

Elles doivent répondre aux critères de qualité reconnus dans la profession.

A cette fin, l'on utilise un appareil « **COULTER PORTABLE DE LA SERIE A^c ● T ou SYSMEX XT-2000I** ».

Pour l'Hb synthétique, l'appareil « **HEMOCUE LOW PLASMA HEMOGLOBINE** » pourra être également employé.

Les résultats obtenus sur place seront communiqués immédiatement sous forme écrite au responsable désigné par l'UCI, soit l'Inspecteur Médical, soit un médecin de la Commission Sécurité et Conditions du Sport.

La totalité des paramètres sanguins sera communiquée au Président de la Commission Sécurité et Conditions du Sport.

5. L'Inspecteur Médical fait mention:

- A. des résultats aux Directeurs Sportifs ou Chefs d'Equipe concernés, en leur restituant la licence des coureurs examinés,
- B. des résultats inacceptables au Président du Collège des Commissaires au moyen du formulaire de l'UCI "Déclaration d'inaptitude",
- C. des valeurs hématocrite aux coureurs selon leurs désirs.

Cette procédure correspond aux conditions de travail idéales au déroulement des contrôles. Les déviations éventuelles ne peuvent donner lieu à des contestations, s'il n'est pas établi qu'elles ont pu influencer la validité des résultats.

Appendix 2: Measurement protocol (UCI)

Juillet 2003

Protocole de mesure de l'hémoglobine plasmatique libre

A. PRISE DE SANG – ECHANTILLONS A ET B

1. Le coureur doit être en position assise.
2. Le garrot ne doit pas être posé trop longtemps inutilement (délai de moins de une minute entre la pose du garrot et l'apparition du sang dans le tube).
3. Deux tubes de 2,7 ml de sang sont prélevés par une ponction unique. Ils sont désignés arbitrairement échantillons A et B. Ils sont étiquetés avec un numéro identique.
Le tube A est roulé au minimum 15 minutes et analysé immédiatement tel que la procédure le décrit ci-dessous dans le point C.
Le tube B est placé dans un flacon numéroté. Le flacon est attribué à l'équipe toute entière. Le numéro du flacon est inscrit sur le formulaire "Contrôle sanguin" sous le point 9.
Cet échantillon peut être utilisé pour une deuxième analyse, en cas de résultat entraînant une déclaration d'inaptitude.
4. Si pour une raison quelconque, le remplissage du deuxième tube présente des difficultés par la même ponction, il sera demandé au coureur s'il désire une deuxième ponction, sinon il admet qu'en cas de résultat entraînant une déclaration d'inaptitude pour l'échantillon A, la deuxième analyse se fera également sur l'échantillon A. Cette condition est acceptée sous le chiffre 11 du formulaire "Contrôle sanguin".
5. En cas de résultat entraînant une déclaration d'inaptitude pour l'échantillon A, le coureur peut demander que l'échantillon B soit ouvert devant lui et analysé suivant les mêmes règles que pour l'échantillon A. Après une contre-expertise, c'est le résultat de l'échantillon B qui sera pris en compte de manière définitive. La demande d'ouverture de l'échantillon B doit être formulée dans un temps raisonnable, après l'annonce du résultat de l'échantillon A, en tenant compte des impératifs de la course et de la qualité des analyses. Ce délai sera discuté le cas échéant entre l'inspecteur médical, le directeur sportif du coureur et le responsable scientifique de l'équipe médicale (cf. art 13.1.055 du règlement UCI).

C. ANALYSE

1. Préparation des sangs et mesures

Les sangs sont roulés pendant 15 minutes au minimum avant l'analyse pour homogénéisation et stabilisation de température.

Après la détermination des valeurs hématiques habituelles (Hct, Hb, réticulocytes), les échantillons seront centrifugés.

2. Coloration du plasma

Protocole de mesure de l'hémoglobine plasmatique libre

La couleur du plasma sera observée. Si le plasma a une **coloration rose/rouge**, l'échantillon sera alors analysé pour l'hémoglobine plasmatique libre, avec les appareils prévus (Coulter, Sysmex ou Hemocue).

Si la valeur d'hémoglobine plasmatique libre est supérieure à **300mg/dl (3g/l)**, on procédera à l'analyse de l'échantillon B.

- **Analyse de l'échantillon B**
 - Le coureur ou son mandataire est alors informé qu'il peut assister, dans un délai défini par l'inspecteur médical, à l'analyse de l'échantillon B.
 - La contre-expertise sera effectuée à l'aide de l'analyseur Coulter ou Sysmex ou Hemocue.
 - **Déroulement de la contre-expertise :**
 - **effectuer deux mesures à l'aide de l'analyseur Coulter ou Sysmex ou Hemocue**
 - **si la valeur est > à 300mg/dl (3g/l) le coureur est déclaré inapte.**

Appendix 3: Information for riders (UCI)

UNION CYCLISTE INTERNATIONALE
COMMISSION SECURITE ET CONDITIONS DU SPORT

Messieurs les coureurs,

Nous aimerions vous donner quelques informations concernant les contrôles sanguins.

Contrôles sanguins

Lors des contrôles sanguins, notamment pendant le Tour de France, les paramètres habituels seront analysés : hématocrite, hémoglobine et réticulocytes.

Si les analyses devaient montrer des profils anormaux (valeurs ou évolutions anormales), on demandera au coureur (ou à son médecin) quelle est l'origine de cette anomalie, et on lui fera savoir qu'il sera davantage contrôlé, car il restera suspect à nos yeux.

Dès cette année, nous utilisons un nouveau protocole pour identifier les coureurs qui ont un profil sanguin non normal.

Il est évident qu'on les soumettra à des contrôles antidopage, pour la recherche de l'EPO ou du NESP.

Hémoglobines synthétiques

Depuis le début de l'année, nous mesurons, lors des contrôles sanguins, un nouveau paramètre : **l'hémoglobine plasmatique libre**. Ce paramètre augmente de façon très importante (plusieurs centaines de fois) en cas d'administration d'hémoglobine synthétique. Comme vous savez, l'Hb synthétique est une substance interdite, et sa commercialisation à plus large échelle est en train de se réaliser. Or, vu qu'elle est encore indétectable lors des contrôles urinaires, il nous fallait trouver une solution pour décourager son éventuelle utilisation, afin de garantir le droit à avoir des compétitions équitables.

Ce paramètre ne peut pas être employé en tant que test antidopage et, par analogie à ce qui se passe avec les valeurs d'hématocrite élevées, un coureur qui aura une valeur d'**hémoglobine plasmatique libre > 300mg/dl (3g/l)** sera donc **déclaré inapte**, et obligé à se soumettre aux investigations hématologiques. L'hémoglobine synthétique, grâce à la détermination de ce paramètre, peut être détectable pendant plusieurs jours.

Nos équipes médicales vont analyser ce paramètre lors de tous les **contrôles sanguins du matin (y compris celui d'aujourd'hui)**, qui se dérouleront de la même façon qu'auparavant (même quantité de sang prélevée).

En restant à votre disposition pour tout renseignement supplémentaire, nous vous souhaitons tout le succès sportif que vous méritez.

Dear Dr. Leon Schatewberg

As President of the Independent Observer Mission during the Tour de France, I want kindly request information about the development of the disciplinary procedures done in the positive case met in the sample A 190775 and confirmed in the sample B 190775, on 1st of August.

I want also to request if UCI develop any other disciplinary procedures concerning the positive reports delivery by the French Antidoping Laboratory in the samples collected during the Tour de France.

Best regards.

**President of Independent
Observer Mission**

Dear Dr. Horta,

I would like to add some information to my last correspondence, As regard to the duration of the proceedings and according art. 113 AER: *"The proceedings before the competent body of the licence-holder's national federation must be completed within one month of the time limit set for the dispatch of the summons."*

We will of course keep you informed all along the procedure. All the documents we will get from the national federation shall be sent to you.

Best Regards,

On behalf of the Antidoping Commission,

Dear Dr. Horta,

I would like to give you the following information as regard to your demand concerning the Tour de France 2003.

The positive case found in the sample A+B 190775 has been and is being managed according to the UCI AER, art. 174 to 183 (Stage races).

The UCI was informed by the laboratory of the B sample result after the Tour de France ended. Therefore, the case has now been transmitted to the rider's national federation for disciplinary procedure.

As far as the corticoids are concerned, the results have been examined by the UCI Antidoping Commission. All cases were justified on medical grounds and were accepted by the Antidoping Commission. For treatments prescribed during the Tour de France, all of them have been prescribed with the cooperation of the UCI medical experts and treatments have been written in the health booklet.

I also invite you to read two articles written by Dr. Gérard Guillaume:

1. Corticothérapie locale et effet systémique (revue de la littérature) publié dans Médecin du Sport ; Gérard Guillaume et Marcel-Francis Kahn ; e-mail address : g-quillaume@wanadoo.fr
2. Intérêts et limite des infiltrations de corticoïdes dans le sport, publié dans journal de traumatologie du sport.

I will try to send you other information and publication as soon as possible.

Best Regards,

On behalf of the Antidoping Commission,

Dr. Leon SCHATTENBERG, President

Cher Philippe Roux-Comeli,

Comme President de la Mission d' Observateurs Independents de l' AMA dans le Tour de France, j'ai reçu les copies des PV sans l' identification des coureurs et les rapports analytiques du LNDD.

J' ai reçu plusieurs rapports analytiques positives pour glucocorticosteroids. J'ai demande des informations à l' UCI sur la gestion de ces resultats. L' UCI a informé que sa Comission Médicale a décidé que tous les rapports positives avec glucocorticosteroids étions justifié par une declaration médicale dans le carnet de santé.

Je suis entrain de finir le rapport de notre mission et je veux savoir si le CPLD a quelque chose a ajouter a la position de l' UCI.

Salutations.

Luis Horta

EXPEDITEUR : Philippe ROUX COMOLI

**DESTINATAIRE : Dr Luis HORTA, Président de la mission O.I. de
l'AMA**

N° DE FAX : 00.35.1.217977529

Monsieur le Président,

Le Président du Conseil de prévention et de lutte contre le dopage a reçu l'ensemble des procès-verbaux et résultats d'analyse relatifs aux contrôles effectués lors du Tour de France 2003.

Outre le cas portant sur l'EPO dont la procédure est en cours, il a transmis un premier courrier à plusieurs coureurs afin de s'assurer que ceux-ci transmettent au Conseil « la preuve d'une prescription médicale à des fins thérapeutiques justifiées ». L'instruction est donc en cours.

En restant à votre entière disposition pour toute information complémentaire, je vous prie d'agréer, Monsieur le Président, l'expression de mes sentiments les meilleurs.

Philippe ROUX COMOLI

Nombre de pages y compris celle-ci : 1

Introduction

Chaque sportif souhaite améliorer ses performances.

La compétition étant au cœur du sport, surtout lorsqu'il se pratique à un haut niveau, il est légitime de chercher à se dépasser. Toujours plus haut, toujours plus fort !

Pour y parvenir, certains sont prêts à toutes les compromissions, y compris à tricher. Certains sont prêts à tous les sacrifices, y compris à se détruire la santé. Le dopage est un miroir aux alouettes. Il donne au corps l'illusion d'accroître ses capacités. En fait, sous dopage, le corps va artificiellement au-delà de ses limites. Cela n'est pas sans conséquences.

Ce guide vise à vous informer sur les risques liés au dopage pour votre santé. Il a pour objectif de vous montrer que le dopage est loin d'être anodin.

Ce guide est également destiné à vous montrer à quel point l'idée du dopage est éloignée du sport. Faire du sport, c'est d'abord prendre soin de son corps. Ceci est vrai quel que soit le niveau auquel on le pratique.

Parce que vous êtes des professionnels, ce message vous concerne tout particulièrement. Vous pratiquez un sport de très haut niveau et la tentation du dopage peut être très présente. Il vous concerne aussi parce que vous êtes un exemple pour les jeunes. Il importe de leur montrer, en particulier à ceux qui courent dans quelques années sur les routes du Tour de France, que l'on peut être performant sans se dopage. Car se dopage, c'est mettre en péril sa santé : pour vous-même, pour les autres sportifs et pour le sport, refuser le dopage c'est vital !

Qu'est-ce que le dopage ?

Pour un sportif, se dopage consiste à consommer des produits interdits ou à recourir à des méthodes prohibées. Dans tous les cas, l'objectif est d'obtenir une amélioration artificielle de ses performances physiques.

Il existe un grand nombre de produits dopants. Schématiquement, on peut les classer en deux grandes catégories : les médicaments et les stupéfiants. Parmi les médicaments, on trouve notamment les bêta-bloquants, les corticoïdes, les anabolisants, les anesthésiques locaux, les diurétiques et l'hormone de croissance.

Un grand nombre de stupéfiants peut être utilisé comme produit dopant. Citons en particulier les stimulants comme la caféine, comme le cannabis, la méthadone, l'héroïne et la morphine, figurent également parmi les stupéfiants.

Tous ces produits ne sont pas totalement interdits. Certains d'entre eux sont à usage restreint. C'est-à-dire qu'ils ne peuvent être utilisés que dans certaines conditions. C'est par exemple le cas des anesthésiques locaux, des corticostéroïdes et des bêta-bloquants.

Par ailleurs, certaines techniques sont utilisées dans le cadre du dopage. Ces méthodes interdites sont le dopage sanguin et les manipulations chimiques, pharmacologique ou physique visant à masquer les substances dopantes dans les échantillons d'urine utilisés lors des contrôles anti-dopage.

Vrai ou Faux ?

Les produits dopants sont dangereux par eux-mêmes.

Faux

C'est la façon de les consommer qui est dangereuse. Certains des produits utilisés pour se dopage sont des médicaments très utiles pour soigner des maladies. Ainsi, il faut bien distinguer l'usage de ces produits et l'abus de leur consommation. C'est l'abus qui est dangereux et qui conduit bien souvent à la dépendance.

Quels sont les risques du dopage ?

Le dopage fait principalement peser des risques pour la santé. La consommation excessive de produits dopants entraîne ainsi de nombreux effets nocifs. Ces derniers peuvent survenir rapidement ou, à l'inverse, apparaître longtemps après la prise du produit dopant (jusqu'à plusieurs années après). A chaque produit sont associés des effets nocifs.

Citons quelques exemples :

Les stimulants (caféine, amphétamines...)

Ils peuvent entraîner des troubles cardio-vasculaires (troubles du rythme cardiaque, infarctus du myocarde, accident vasculaire cérébral), des troubles neurologiques et neuro-musculaires (troubles de la coordination, par exemple) et des troubles psychiques (agressivité ou dépression entre autres).

Les stéroïdes anabolisants

Chez l'homme, ils provoquent des atteintes au niveau de la prostate et du foie, une augmentation de la taille des seins, des troubles du fonctionnement des testicules, une production réduite des spermatozoïdes (avec un risque d'infertilité).

Les diurétiques

Ils peuvent provoquer une déshydratation aiguë, des troubles cardio-vasculaires, une fatigue et un état de faiblesse généralisée, ainsi qu'un dysfonctionnement des reins.

Les hormones peptidiques

(EPO, hormones de croissance, DHEA) : les principaux effets indésirables de ces produits sont la survenue d'une insuffisance cardiaque sévère (pouvant entraîner un infarctus du myocarde, voire une mort subite), d'un diabète, de troubles sexuels et de cancers.

Tous les sportifs recourant à des produits dopants ne présentent pas systématiquement l'ensemble de ces troubles. Il existe en fait une variation importante d'une personne à une autre. Certains seront plus sensibles que d'autres aux effets indésirables d'une consommation de substances dopantes, sans que l'on puisse prédire à l'avance le degré de sensibilité de chacun. Mais il n'existe pas d'individu qui soit totalement insensible aux effets néfastes des produits dopants.

Le saviez-vous ? Le saviez-vous ?

On considère que la durée de vie des sportifs qui se dopent est inférieure d'une vingtaine d'années en moyenne à celle de la population générale

Comment se passer du dopage ?

Le dopage n'est pas une fatalité, même dans le sport de très haut niveau. De très nombreux champions ont connu de grande carrière sans recourir aux produits dopants. Comment ont-ils fait, comment vous pouvez faire ?

En fait, pour pratiquer un sport, quel que soit son niveau, sans user de substance dopante, il n'y a pas de « recette miracle » ! La performance repose sur les principes de base que sont l'entraînement, la récupération, l'hygiène de vie, le suivi médical et le travail d'équipe.

5 conseils pour améliorer vos performances sans dopage

1 L'entraînement : c'est la base de toute pratique sportive. Sans entraînement, on ne peut maintenir son organisme en situation de réaliser l'activité que l'on souhaite pratiquer. On ne peut pas non plus progresser dans ses performances. L'entraînement doit être adapté à chaque personne, en modulant l'intensité, le volume et la répétition des activités physiques.

2 La récupération : elle est tout aussi essentielle. Sinon, l'organisme se fatigue à l'excès et il devient moins performant. La récupération repose sur l'alternance « travail - repos » qui doit respecter le rythme entre l'éveil et le sommeil. Les techniques de relaxation, le stretching (méthode basée sur des étirements) et l'hydratation favorisent la récupération.

3 L'hygiène de vie : pratiquer un sport suppose une hygiène de vie adaptée. Celle-ci nécessite de respecter ses rythmes biologiques. Par ailleurs, chaque sportif sait combien l'alimentation est importante. Il est donc essentiel d'adopter de bonnes habitudes alimentaires.

4 Le suivi médical : il est très important d'être suivi sur le plan médical très régulièrement. Le médecin doit pouvoir ainsi s'assurer de vos aptitudes à votre activité sportive, tout à la fois sur le plan médical, biologique et psychologique. La relation engagée avec le médecin doit permettre de mettre sur pied une véritable « stratégie de santé ».

5 Le travail d'équipe : dans le cyclisme, la performance est le fruit du travail de toute une équipe. Vous le savez, auprès de vous intervient l'entraîneur, le préparateur physique, le kinésithérapeute, le psychologue et le médecin. Il est important que chacun exerce ses talents dans le respect des autres et des règles. C'est comme cela que les équipes gagnent !

Appendix 10: Tour de France Code of Ethics

>> Le code éthique du Tour de France

Le Tour de France possède en propre des valeurs sans lesquelles il perdrait non seulement sa crédibilité sportive, mais encore son indiscutable fonction culturelle, économique et sociale.

Ces valeurs de référence conservent une signification à travers le temps, tout en prenant en compte les notions de compétition, d'affrontement, de dépassement et en finalité l'objectif majeur de victoire.

Mais il ne peut s'agir ni de n'importe quelle compétition, ni de victoire obtenue à n'importe quel prix.

Comme toutes les activités sportives, comme les autres épreuves cyclistes et davantage encore parce qu'il est la plus prestigieuse de toutes, le Tour de France doit donc s'accompagner :

- De règles précises, dont ni la lettre ni l'esprit ne doivent être transgressés.
- Du respect des officiels chargés de l'application de ces règles et des décisions qu'ils peuvent être amenés à prendre.
- De l'égalité des chances offertes aux concurrents. L'avantage accordé à l'un d'entre eux d'une manière illicite est contraire à l'éthique sportive. C'est en ce sens que le dopage, trop souvent présent dans l'activité sociale ordinaire, est inadmissible en sport.
- D'une action rigoureuse menée contre la tricherie, la corruption et toute forme d'arrangement permettant de vaincre autrement que par les moyens du sport.

L'acceptation de ces principes conditionne l'estime et la popularité qu'accorde au Tour de France un public nourri par une longue période d'exploits et de légende.

Les champions d'aujourd'hui ont en héritage un patrimoine qui ne saurait aller sans les vertus morales qui ont contribué à le forger.

Tout coureur cycliste, quels que soient la place qu'il occupe et le niveau de ses performances, est par conséquent tenu de respecter cette éthique fondamentale. A défaut, il risquerait de conduire son sport vers la perversion et la décadence.

EDUCATION

May, 1982

B.A. degree in Zoology
Drew University
Madison, New Jersey

August, 1985

M.S. degree in Forensic Toxicology
University of Maryland School of Medicine
Department of Pathology, Division of Forensic Pathology
Baltimore, Maryland

Thesis: “*In vitro* and *in vivo* studies of the collection and delayed analysis of the alcohol content in breath.”

January, 1993

Ph.D. degree in Forensic Toxicology
University of Maryland School of Medicine
Department of Pathology, Division of Forensic Pathology
Baltimore, Maryland

Dissertation: “Measurement and interpretation of heroin, 6-acetylmorphine and morphine concentrations in biological tissues obtained from heroin users and heroin-related deaths.”

PROFESSIONAL POSITIONS

| | |
|---------------------------------------|--|
| July, 2005 to present | Professor, Clinical Track Department of Pathology, Immunology and Laboratory Medicine Department of Psychiatry University of Florida College of Medicine Gainesville, Florida |
| November, 2002 to June 2005 | Associate Professor, Clinical Track Department of Psychiatry University of Florida College of Medicine Gainesville, Florida |
| July, 2001 to June 2005 | Associate Professor and Director of Toxicology, Clinical Track Department of Pathology, Immunology and Laboratory Medicine University of Florida College of Medicine Gainesville, Florida |
| July, 1999 to June, 2001 | Assistant Professor and Director of Toxicology, Clinical Track Department of Pathology, Immunology and Laboratory Medicine University of Florida College of Medicine Gainesville, Florida |
| October, 1994 to June, 1999 | Assistant Professor and Director of Toxicology Department of Pathology, Immunology and Laboratory Medicine University of Florida College of Medicine Gainesville, Florida |
| September, 1987 to September, 1994 | Toxicologist National Center for Forensic Science a division of Maryland Medical Laboratory Baltimore, Maryland |
| September, 1989 to May, 1992 | Assistant Toxicologist and Toxicology Laboratory Manager Toxicology Laboratory Office of the Chief Medical Examiner Baltimore, Maryland |
| July, 1986 to September, 1989 | Assistant Toxicologist Toxicology Laboratory Office of the Chief Medical Examiner Baltimore, Maryland |

September, 1982
to September, 1987

Laboratory Technologist
Clinical Toxicology Department
Maryland Medical Laboratory
Baltimore, Maryland

CERTIFICATIONS

Diplomate. American Board of Forensic Toxicology, Certificate Number 218 (3/1/99-6/30/09)
Clinical Laboratory Director. Board of Clinical Lab Personnel, Department of Business and Professional Regulation, State of Florida, License Number DI 0033647 (5/18/95-8/31/06)
Forensic Toxicology Specialist. American Board of Forensic Toxicology, Certificate Number 5001 (11/1/92-2/28/99)
Toxicological Chemist. National Registry of Certified Chemists (previously known as the National Registry in Clinical Chemistry), Certificate Number 2254 (1991-2006)

HONORS AND AWARDS

Educational Research Award. Society of Forensic Toxicologists, 1984 and 1986
Sunshine Award. Toxicology Section, American Academy of Forensic Sciences, 1988
Toxicology Section Scholarship. American Academy of Forensic Sciences, 1991
Outstanding Scientific Achievements by a Young Investigator Award. American Association for Clinical Chemistry, 1994
Mid-Career Achievement Award, The International Association of Forensic Toxicologists, 2004
Alexander O. Gettler Award, Toxicology Section, American Academy of Forensic Sciences, 2006

CAMPUS ACTIVITIES

Teaching

College of Medicine:

General Pathology and Immunology (BMS 5608) – Lectures in Chemical Carcinogenesis and Forensic Pathology
Systemic Pathology and Laboratory Medicine (BMS 5600) Case Study Mentor
Principles of Drug Action (GMS 6002) – Forensic Pharmacology (Grand Rounds)
Special Topics in Pathology: Cellular & Molecular Basis of Liver Disease (GMS 6381) – Lecture in Pharmacogenomics and Drug Toxicity
Translational Neuroscience: Junior Honors Medical Program (MEL 4001) – Forensic Medicine
Laboratory Rotation Mentor, Interdisciplinary Graduate Program
Pathology Resident Rotation (Preceptor)

College of Pharmacy:

Selected Topics in Pharmacy (The Role of the Pharmacist in Substance Abuse Education and Prevention; PHA 4933) – Lecture in Forensic Toxicology

College of Law:

Handling Drug/Alcohol Crimes Seminar – Lecture in Forensic Toxicology

Thesis/Doctoral Dissertation Committee Member:

Michael W. Belford, Department of Chemistry, 2001-2003
 Matthew W. Warren, Department of Psychiatry, 2003-2006
 Timothy L. Naylor, Department of Physiological Sciences, 2003-present
 Frank Kero, Department of Chemistry, 2004-present
 David Khey, Department of Criminology, Law and Society, 2005-present

Student/Fellowship Training:

| <u>Name</u> | <u>Program</u> | <u>Date</u> |
|------------------------------------|---|--------------|
| Diana Garside | Post-Doctoral Fellowship in Forensic Toxicology | 1994-1997 |
| Jeri Roper-Miller | Graduate Student – Doctoral | 1994-1998 |
| Ruth Winecker | Graduate Student – Doctoral | 1994-1996 |
| Jason Byrd | Graduate Student Rotation | 1996 |
| Bart Wacek | Graduate Student Intern | 1996 |
| Mary Rucker | Graduate Student – IDP Lab Rotation | 1998 |
| Richard Fox | Center for Precollegiate Education and Training | 1998 |
| Gretchen Miller | Graduate Student – Master's | 1998-1999 |
| Beth Ladlie | Graduate Student – IDP Lab Rotation | 1998 |
| Tara Sabo | Graduate Student – IDP Lab Rotation | 1999 |
| Andria Hobbs | Undergraduate Student – University Scholars Program | 1999-2000 |
| Kristofer Rau | Graduate Student – IDP Lab Rotation | 1999 |
| Jessica Walrath | Graduate Student – IDP Lab Rotation | 2000 |
| Bruno De Martinis | Visiting Scientist (Brazil) | 2000-2001 |
| Karen Vieira | Graduate Student – IDP Lab Rotation | 2001 |
| Michele Merves | Graduate Student – Doctoral | 2001-2007 |
| Sheng-Meng Wang | Visiting Scientist (Taiwan) | 2001 |
| María Antonia Martínez González | Visiting Scientist (Spain) | 2002 |
| Michele Merves | Graduate Student – Doctoral | 2002-present |
| Rebecca Murray | Pharmacy Student | 2002-2003 |
| Ansley Gascoigne | Undergraduate Intern (UCF) | 2004 |
| Kelly MacDougall | Graduate Student – IDP Lab Rotation | 2005 |
| Rebecca Fidler | Undergraduate Intern (UCF) | 2005 |
| Jennifer Hoyer | Undergraduate Intern (UCF) | 2005 |

| | | |
|---------------------|--|------|
| Christopher Moody | Undergraduate Intern (UCF) | 2005 |
| Melissa Clarady | Undergraduate Intern (UCF) | 2006 |
| Kimberly Fitzgerald | Medical Student (UF College of Medicine) | 2006 |
| Melanie Atkinson | High School Student (PK Young) | 2006 |
| Jenna Chin | Undergraduate (UF Senior Research) | 2006 |
| Sarah Guilmain | Graduate Student – IDP Lab Rotation | 2006 |

Administration

College of Medicine

Member, Medical Selection Committee, 2005-present

Department of Pathology, Immunology and Laboratory Medicine:

Director, William R. Maples Center for Forensic Medicine
Unit Director of Toxicology, Diagnostic Referral Laboratories
Member, Diagnostic Referral Laboratories Executive Committee
Member, Diagnostic Referral Laboratories Quality Assurance Group
Chairman, Biosafety Committee
Biologic Safety Officer
Member, Clinical Research Committee
Member, Rocky Points Labs, Building & Safety Committee

Interdisciplinary Toxicology Graduate Training Program (Center for Environmental and Human Toxicology):

Faculty Member
Graduate Coordinator for Pathology
Member, Toxicology Graduate Specialization Committee

University of Florida University Athletic Association:

Member, University Athletic Association Substance Abuse Committee

OTHER ACADEMIC ACTIVITIES

Adjunct Assistant Professor in Clinical Chemistry. University of Maryland School of Medicine,
Department of Medical and Research Technology, Baltimore, Maryland, 1991-1992 and
1993-1994

Thesis Advisor. College of Graduate Studies, Thomas Jefferson University, Philadelphia,
Pennsylvania, 1994

External Examiner for Sarah Kerrigan. Faculty of Graduate Studies, The University of British
Columbia, Vancouver, B.C. Canada, 1997

PROFESSIONAL MEMBERSHIPS AND ACTIVITIES

American Academy of Forensic Sciences (AAFS), Fellow, 1983-present

Academy Activities

Program Committee, Poster Session Chairman, 1994
Nominating Committee, 1996-1997
Council, 1995-1997
Program Committee, Breakfast Seminars Chairman, 1997-1998
Program Committee, Poster Session Chairman, 1998-1999
Strategic Planning Committee, 1997-1998
Long Term Planning Committee, 1998-present
Board of Directors (Toxicology Section Representative), 1999-2002
Academy-Wide Luncheons, Moderator, 2000
Program Committee, Workshop Chairman, 2000-2001
Forensic Sciences Foundation Nominating Committee, 2000-2001
Program Committee, Program Co-Chairman, 2001-2002
Program Committee, Program Chairman, 2002-2003
Policy and Procedure Committee, 2002-present
AAFS Website Redesign Task Force (Chairman), 2002-2003
AAFS Website Content Oversight Task Force, 2003-2004
Vice President, 2003-2004
Membership Committee, Chairman, 2003-2004
Treasurer, 2004-2006
Executive Committee, 2004-present
Finance Committee, 2006-present
Forensic Sciences Foundation Nominating Committee, 2005-2006
President-Elect, 2006-2007
Trustee, Forensic Sciences Foundation, 2006-2008
President, 2007-2008

Toxicology Section Activities

Workshop Co-Chairman, 1992-1995, 1999
Program Committee, 1992-1996
Program Chairman, 1994-1995
Secretary, 1995-1996
Chairman, 1996-1997
Chairman, Nominating Committee, 1997-1998
Abstract Guidelines Committee, 1995-1996
Editor, *News and Views*, 1993-1996
Steering Committee, 1994-present
Minutes Review Committee, 1994-1999
Awards Committee, 1997-1999, 2001-present
ad hoc Membership Guidelines Committee, 1994-1999

American Association for Clinical Chemistry (AACC), Member, 1984-present

TDM/Tox LIP Committee, 1991-1996; Chairman, 1995-1996
FUDT/LIP Committee, 1997-present; Chairman, 1999
Toxicology News Committee, Chairman, 2000-2001

Workshop Leader, 1993-1994
TDM and Clinical Toxicology Division, representative to the Joint Committee on Education and Training in Toxicology, 1993-1996
American Board of Forensic Toxicology (ABFT)
Board of Directors, 2000-present
Treasurer, 2002-present
Promotion Committee, 1998-present
Examination Committee, 1999-present
Finance Committee, 2002-present
California Association of Toxicologists (CAT), Associate Member, 1993-present
Council of Science Editors, 2001-present
National Academy of Clinical Biochemistry, Fellow, 2003-present
International Association for Chemical Testing (IACT), Member, 1999-present
National Committee for Clinical Laboratory Standards, Member, 1993-2002
Gas Chromatography/Mass Spectrometry (GC/MS) Confirmation of Drugs Committee
National Registry of Certified Chemists (NRCC)
Board of Directors, 2001-2003
Examination Committee, 2001-2003
National Safety Council, Committee on Alcohol and Other Drugs, Member, 1988-present
Education and Training, Co-Chairman, 1990-1991
Education and Training, Chairman, 1992-1997
Executive Board, 1992-present
Action Programs Subcommittee, 1998-present
Web-Site (ad hoc) Subcommittee, Chairman, 2002-present
Society of Forensic Toxicologists (SOFT), Member, 1984-present
Advisory Committee on Hair Analysis, 1991-1992
Annual Meeting Program Committee, 1993-present
Chairman, SOFT Web-site Committee, 1997-present
Chairman, SOFT Logo Redesign Committee, 1997
Board of Directors, 1998-2000
Special Issue Editor, Journal of Analytical Toxicology, 1999
Board of Directors (ex officio), 2005-present
The International Association of Forensic Toxicologists (TIAFT), Member, 1991-present
T'2007 Scientific Advisory Committee, 2006-present

EDITORIAL TASKS

Clinica Chim Acta – Member, Editorial Board, 1999-2003
Clinical Chemistry - ad hoc reviewer, 2006
Clinical and Forensic Toxicology News (AACC Newsletter) – Chairman, Editorial Advisory Board, 1999-2001
Drug Court Review – ad hoc reviewer, 2005
Forensic Science International – ad hoc reviewer, 2004-2006
Forensic Science Review – Member, Board of Editors, 2002-present
Journal of Analytical Toxicology –
Editor-in-Chief, 2001-present

Member, Editorial Advisory Board, 1997-2000
Invited Reviewer, 1995-1996
Society of Forensic Toxicologists Special Issue Editor, October, 1999
Journal of Forensic Sciences – Member, Editorial Board, 1997-present
Science & Justice – ad hoc reviewer, 2005
Therapeutic Drug Monitoring and Toxicology (AACC In-Service Training and Continuing Education Publication) – Chairman, Editorial Board, 1995-1996
Clarke's Isolation and Identification of Drugs (3rd Edition), Pharmaceutical Press – Member, Editorial Board, 2000-present

CONSULTANT AND OTHER RELATED ACTIVITIES

Expert Witness/Consultant in Forensic Toxicology. Qualified as an Expert in Forensic Toxicology in Federal, State of Florida, Canadian, and Military Courts of Law
Laboratory Inspector. National Laboratory Certification Program, Substance Abuse and Mental Health Services Administration, DHHS, 1989-2000
Chairman. Florida Department of Law Enforcement/Institute of Police Technology and Management Implied Consent Rules Committee, 1999-2000
Chairman. Substance Abuse Committee, Athletic Programs, Santa Fe Community College, 1997-present
Co-Chair, Methadone Associated Mortality: A National Assessment Workshop, Center for Substance Abuse Treatment Substance Abuse and Mental Health Services Administration, Arlington, Virginia, May 2003
Member. Florida Task Force on Suicide Prevention, Office of Drug Control, Office of the Governor, State of Florida, 2003-present
Consultant, Drug Enforcement Administration (Arlington, VA), 2004-present
Consultant, National Football League Players Association (Washington, D.C.), 2006-present

REVIEW OF GRANTS AND CONTRACTS

Consultant. Counterdrug Technology Assessment Center Demand Reduction Advisory Board, Office of National Drug Control Policy, Executive Office of the President, 1993
Consultant. Maternal Lifestyle Study, National Institute of Child Health and Human Development, National Institutes of Health, 1992-1993
Consultant. Measurement of Caffeine, Paraxanthine and Osmolality in Serum from the Collaborative Perinatal Project, National Institute of Child Health and Human Development, National Institutes of Health, 1996
ad hoc Committee Member. Molecular, Cellular and Chemical Neurobiology Research Review Subcommittee [NIDA/B], National Institute on Drug Abuse Initial Review Group, National Institutes of Health, 1996-1997
ad hoc Reviewer. Clinical Protocols, Addiction Research Center, National Institute on Drug Abuse, National Institutes of Health, 1998
ad hoc Committee Member. Epidemiology and Prevention Review Committee [NIDA/G], National Institute on Drug Abuse Initial Review Group, National Institutes of Health, 1998
ad hoc Reviewer. NIDA/INVEST Research Fellowship Program, National Institute on Drug Abuse, National Institutes of Health, 2000

Reviewer. FY 2005 General Forensics Research and Development Solicitation, Office of Science and Technology, National Institute of Justice, U.S. Department of Justice, 2005

Reviewer. FY 2006 Forensic Toxicology Research and Development (R&D) Solicitation, Office of Science and Technology, National Institute of Justice, U.S. Department of Justice, 2006

INVITED LECTURES

The Use of Quality Control by Forensic Urine Drug Testing Laboratories. Hewlett-Packard Clinical/Forensic Seminar, Rockville, Maryland, April, 1989.

Principles of Forensic Toxicology. Forensic Toxicology Workshop, Department of Health and Rehabilitation Services, State of Florida, Orlando, Florida, April, 1990.

Drug Testing in the 1990s. 1991 Hewlett-Packard User's Group Meeting, American Society of Mass Spectrometry, Nashville, Tennessee, May, 1991.

Optimization of GC/MS. Hewlett-Packard User's Group Meeting, Baltimore, Maryland, October, 1991.

FPDT: Forensic Pelage Drug Testing (Breakfast Seminar). American Academy of Forensic Sciences, New Orleans, Louisiana, February, 1992.

Optimization of GC/MS. Forensic and Clinical Drug Analysis by GC/MS. Hewlett-Packard Sponsored Workshop, American Association for Clinical Chemistry, Chicago, Illinois, July, 1992.

Confirmation. Preparing for the NIDA NLCP Inspections: Problems Commonly Encountered by Inspectors. Society of Forensic Toxicologists, Cromwell, Connecticut, October, 1992.

Hair Testing: The Growing Way to Test for Drugs of Abuse. The Pittsburgh Conference, Atlanta, Georgia, March, 1993.

Disposition of Heroin and 6-Acetylmorphine in Hair. Clinical Pharmacology/Toxicology Forum, Baltimore, Maryland, March, 1993.

Testing for Abused Drugs in Human Hair. 1993 Hewlett-Packard User's Group Meeting, American Society of Mass Spectrometry, San Francisco, California, May, 1993.

Hair. Drug Analysis of Unusual Biological Tissues. American Association for Clinical Chemistry, New York, New York, July, 1993.

Heroin and Metabolites in Biological Tissues Obtained from Heroin Users and Heroin-Related Deaths. Roche Diagnostics Seminar, Branchburg, New Jersey, August, 1993.

Seminar: Measurement and Interpretation of Heroin, 6-Acetylmorphine and Morphine Concentrations in Biological Tissues. Department of Medical and Research Technology, University of Maryland School of Medicine, Baltimore, Maryland, September, 1993.

Study of the Effect of "UrinAid" on HHS Regulated Urine Specimens. Drug Testing Advisory Board, Division of Workplace Programs, Substance Abuse and Mental Health Services Administration, Bethesda, Maryland, September, 1993.

Current Status of Hair Drug Testing. Capital Section, American Association for Clinical Chemistry, Baltimore, Maryland, November, 1993.

Optimization Techniques for GC/MS. The In's and Out's of Capillary Gas Chromatography: Routinely Utilized Inlet and Detector Systems. American Academy of Forensic Sciences, San Antonio, Texas, February, 1994.

Opiates. Forensic Toxicology. Armed Forces Institute of Pathology, Vienna, Virginia, April, 1994.

Adulteration Issues-Laboratory Checks and Balances. Substance Abuse Workshop. Department of Energy, Alexandria, Virginia, May, 1994.

- Hair. Drug Analysis of Unusual Biological Tissues. American Association for Clinical Chemistry, New Orleans, Louisiana, July, 1994.
- Pharmacology of Heroin and Related Opiates in Hair. SOFT Conference on Drug Testing in Hair, Tampa, Florida, October, 1994.
- Opiates. Fundamentals of Forensic Toxicology: A Basic Course. Society of Forensic Toxicologists, Baltimore, Maryland, October, 1995.
- Testing for Drugs in Hair. Seminar. Departments of Pharmacodynamics and Pharmaceutics, University of Florida College of Pharmacy, Gainesville, Florida, October, 1995.
- Postmortem Toxicology. Advances in Alcohol and Drug Testing-Significance for Legal Proceedings. Toxicology Consultants Forensic Science CLE Seminar Series. Fort Lauderdale, Florida, December, 1995.

PUBLICATIONS

Books

1. Liu RH and Goldberger BA (eds). Handbook of Workplace Drug Testing. AACC Press, 1995 (380 pages) [second printing 1996 – 396 pages; Chinese translation 1997 – 448 pages].
2. Jenkins AJ and Goldberger BA (eds). On-Site Drug Testing. Humana Press, Inc., 2002 (276 pages).

Chapters

1. Goldberger BA and Cone EJ: Heroin. *in* Encyclopedia of Analytical Science. Academic Press, 1995 (pp. 3861-3866).
2. Inoue T, Seta S and Goldberger BA: Analysis of drugs in unconventional samples. *in* Handbook of Workplace Drug Testing. AACC Press, 1995 (pp. 131-158).
3. Garside D and Goldberger BA: Determination of cocaine and opioids in hair. *in* Drug Testing in Hair. CRC Press, Inc., 1996 (pp. 151-180).
4. Winecker RE and Goldberger BA: Urine specimen suitability for drug testing. *in* Drug Abuse Handbook. CRC Press, Inc., 1998 (pp. 764-772).
5. Goldberger BA and Jenkins AJ: Drug Toxicology. *in* Sourcebook on Substance Abuse: Etiology, Epidemiology, Assessment, and Treatment. Allyn & Bacon, 1999 (pp. 184-196).

6. Kerrigan S and Goldberger BA: Opioids. *in* Principles of Forensic Toxicology. AACC Press, 1999 (pp. 202-220). {revised – 2003}
7. Magura S, Laudet A and Goldberger BA: Improving the validity of behavioral drug abuse research through drug testing. *in* Drug Testing Technology: Assessment of Field Applications. CRC Press, 1999 (pp. 215-233).
8. Garside D and Goldberger BA: Forensic and Medicolegal Issues. *in* Atlas of Hair and Nails. Churchill Livingstone, 1999 (pp. 227-232).
9. Kerrigan S and Goldberger BA: Drugs of Abuse - Body Fluids. *in* Encyclopedia of Forensic Sciences. Academic Press, 2000 (pp. 616-626).
10. Ropero JD and Goldberger BA. Opioids. *in* The Clinical Toxicology Laboratory - Contemporary Practice in Clinical Toxicology. AACC Press, 2001 (pp. 73-96).
11. Caplan YH and Goldberger BA: Blood, Urine and Other Fluid and Tissue Specimens for Alcohol Analyses. *in* Medical-Legal Aspect of Alcohol, fourth edition. Lawyers & Judges Publishing Company, 2003 (pp. 149-159).
12. Merves ML and Goldberger BA: Heroin. *in* Encyclopedia of Analytical Science, second edition. Elsevier Press, 2005 (pp. 260-266).
13. Kerrigan S and Goldberger BA: Forensic Toxicology. *in* Forensic Nursing. Elsevier Mosby Publishing, 2005 (pp. 123-139).
14. Kerrigan S and Goldberger BA: Substance Misuse – Alternative Body Fluids Analysis. *in* Encyclopedia of Forensic and Legal Medicine. Elsevier Press, 2005 (pp. 192-201).
15. Isenschmid DS and Goldberger BA: Workplace Testing – Analytical Considerations and Approaches for Drugs. *in* Drug Abuse Handbook, second edition. CRC Press, Inc., 2007 (pp. 775-799).
16. Merves ML and Goldberger BA: Quality Assurance, Quality Control, and Method Validation in Chromatographic Applications. *in* Chromatographic Methods in Clinical Chemistry and Toxicology. John Wiley & Sons, Ltd., 2007 (pp. 1-14).
17. Merves ML and Goldberger BA: Forensic Toxicology. *in* Forensic Chemistry. John Wiley & Sons, Inc. (in press).
18. Kerrigan S and Goldberger BA: Specimens of Maternal Origin – Amniotic Fluid & Breast Milk. *in* Drug Testing in Alternative Biological Specimens. Humana Press, Inc. (in press).

Monographs

1. Goldberger BA: Acetaminophen, Caffeine, Chloramphenicol, Lithium and Procainamide Drug Monographs. *in* Drug Monitoring Data Pocket Guide II. AACC Press, 1994.
2. Goldberger BA: Opiates. Abused Drugs Monograph Series. Abbott Diagnostics, 1994.
3. Goldberger BA, Roper-Miller JD, Zawta B and Jackson R: Drugs of abuse testing. Questions and Answers. Boehringer Mannheim Corporation, 1998. {revised and reprinted by Roche Diagnostics in 1999}
4. Hammett-Stabler C, Goldberger BA and Roper-Miller JD: Abused drugs. *in* Medical Toxicology Self Study. American Association for Clinical Chemistry, 1998.
5. Roper JD, Garside D and Goldberger BA. Opiates. *in* Contemporary Practice in Clinical Toxicology. American Association for Clinical Chemistry, 1998. {second edition, 2000}
6. Goldberger BA (ed.): Hair Analysis: Drugs of Abuse, Therapeutic Drugs, and Steroids {reprints of selected articles from the Journal of Analytical Toxicology}, 2001.

March 27, 2007

Curriculum Vitae

Allen C. Lim, PhD

April 2007

Date of Birth: December 1, 1972

Place of Birth: Davao City, Philippines

Business Address:

1118 13th Street, #A30

Boulder, CO 80302

303-396-8845

E-mail: allen@slipstreamsports.com

Home Address:

770 Walnut, Unit D

Boulder, CO 80302

720-938-3094

E-mail: allenlim@mac.com

Education:

1998-2004

University of Colorado at Boulder

Department of Integrative Physiology

Doctor of Philosophy, Applied Exercise Science

1994-1996

University of Colorado at Boulder

Department of Kinesiology

Master of Science, Kinesiology

1990-1994

University of California at Davis

Department of Physical Education

Bachelor of Science, Exercise Science

Professional Experiences:

2006-Present

Sports Physiologist: Slipstream Sports Professional Cycling Team. Boulder, Colorado & Gerona, Spain.

2005-2006

Sport Science Consultant: Phonak Professional Cycling Team. Switzerland.

2005-Present

President & Founder: 99 One, Inc. Sports Science & Consulting Services. Boulder, Colorado.

2003-Present

Director of Education: Saris Cycling Group, manufacturers of the CycleOps PowerTap. Madison, Wisconsin.

2005-2006

Sport Science Consultant: Phonak Professional Cycling Team

1998-2000

Consultant: E-Tune, Developers of the PowerTap rear hub power meter. Boston, Massachusetts.

1998

Wellness Consultant: Center for Creative Leadership, Colorado Springs, Colorado.

1998-2004

Exercise Test Technologist: University of Colorado

1994-1996

Community Wellness and Education Program. Boulder, Colorado.

Academic Appointments:

2002

Instructor: Exercise Physiology, CU Boulder

2002-2003

Teaching Assistant: Statistics, CU Boulder

2002-2003

Teaching Assistant: Nutrition, CU Boulder

1995-1998

Instructor: "Electrocardiography & Exercise Stress Testing"

| | |
|-----------------------|---|
| Fall 2000-Spring 2001 | University/Community Wellness and Education Program. <i>Lab Director & Teaching Assistant:</i> Exercise Physiology, CU Boulder |
| Fall 1998 | <i>Teaching Assistant:</i> Neuromuscular Physiology, CU Boulder. |
| Fall 1998 | <i>Teaching Assistant:</i> Statistics, CU Boulder. |
| Fall 1995-Spring 1996 | <i>Teaching Assistant:</i> Exercise Physiology, CU Boulder. |
| Spring 1995 | <i>Laboratory Assistant:</i> Human Performance Lab, CU Boulder. |

Grants and Fellowships Received:

| | |
|---------------------|--------------------------------------|
| 2001-2004 | Saris Cycling Group Research Grant. |
| Spring 00 – Fall 01 | Dean's Fellowship Award. |
| Fall 99 – Spring 00 | Dean's Fellowship Award. |
| Fall 1999 | University Fellowship Award. |
| Spring 1999 | Celestial Seasonings Research Grant. |
| Spring 1996 | Deans Small Grant. |
| Fall 1995 | Graduate School Fellowship Award. |

Research Experience:

| | |
|-------------|--|
| 2003-2004 | <i>Primary Investigator:</i> "Physiological vs. physical determinants of uphill vs. level time trial performance." CU Boulder. |
| 2002-2003 | <i>Primary Investigator:</i> "Predicting aerodynamic drag using a rear hub power meter." CU Boulder. |
| 2000 | <i>Primary Investigator:</i> "Heart Rate vs. Power in men and women during a National Calendar stage race." CU Boulder |
| 2004 | <i>Co-Investigator:</i> "Cycling performance at moderate altitude versus sea level simulated with a hyperoxic gas." CU Boulder. |
| 2000-2004 | <i>Co-Investigator:</i> "Bone density in professional cyclists." CU Boulder. |
| 1999-Date | <i>Co-Investigator:</i> "The influence of pedal cadence on uphill cycling performance and economy." CU Boulder. |
| 1999-Date | <i>Co-Investigator:</i> "Maximal sustainable power at fixed percentages of peak power output." CU Boulder. |
| 1998-Date | <i>Primary Investigator:</i> "The physical and physiological demands of competition and training in elite cyclists." CU Boulder. |
| 1999 | <i>Co-Investigator:</i> "The reliability and validity of the Power Tap® rear bicycle hub dynonameter." CU Boulder. |
| Summer 1997 | <i>Research Assistant:</i> "Work fitness of commercial porters of Eastern Nepal." CU Boulder. |
| 1995-1996 | <i>Primary Investigator:</i> "Exercise induced desaturation in elite female cyclists." Department of Kinesiology, CU Boulder & The USOC Sport Science & Technology Division, Colorado Springs, Colorado. |
| 1994 | <i>Lab Assistant:</i> "The relationship of pulmonary ventilation and heart rate in arm work alone, leg work alone, and in various combinations of arm and leg work when exposed to moderate and hot ambient temperatures." Investigators: Adams, W.C., & J.D. Shaffrath, Department of Exercise Science, University of California at Davis. |

Publications:

| | |
|-----------|---|
| In Review | Lim, A.C., Carver, T.C., Edwards, A.G., Byrnes, W.C. "Physiological vs. physical determinants of uphill vs. level time trial performance." <i>Medicine & Science in Sports & Exercise</i> . |
| In Review | Edwards, A.G., Lim, A.C., and Byrnes, W.C. "Predicting aerodynamic drag using a rear hub power meter." <i>Medicine & Science in Sports & Exercise</i> . |
| In Review | Turner, B.T., Lim, A.C., and Byrnes, W.C. "The influence of pedal cadence on uphill cycling performance and economy." <i>Medicine & Science in Sports & Exercise</i> . |
| In Review | Ziewacz, D.C., Lim, A.C., and Byrnes, W.C. "The reliability and validity of the Power Tap® rear bicycle hub dynamometer." <i>Medicine & Science in Sports & Exercise</i> . |
| 2001 | Malville, NJ, Byrnes WC, Lim, AC, Basnyat, R. Commercial porters of eastern Nepal: health status, physical work capacity, and energy expenditure. <i>American Journal of Human Biology</i> . Vol 13, No. 1, pp. 44-56. Jan 2001. |
| 1998 | Lim, A.C. Heat and cold stress in competitive cycling. United States Cycling Federation Elite Coaching Manual. 1998. |
| 1997 | Lim, A.C., W.C. Byrnes, R.L. Wilber, and J.T. Kearney. Exercise-induced desaturation in elite female and male cyclists at moderate altitudes. Abstract. <i>Medicine & Science In Sports & Exercise</i> . Vol. 29, No. 5, P. S286, May 1997. |

Certifications & Memberships:

| | |
|-----------|--|
| 1995-Date | <i>Exercise Test Technologist:</i> ACSM Certification # 3840 |
| 1998-Date | <i>Member:</i> American College of Sports Medicine |

Coaching Experience:

| | |
|-----------|---|
| 2007 | <i>Coach:</i> Slipstream-Chipotle Professional Cycling Team 3 rd place, World Track Championship Omnium Most Aggressive Rider, Tour of California |
| 2006 | <i>Sports Physiologist & Training Advisor:</i> Floyd Landis, Winner of the 2006 Tour de France. |
| 2006 | <i>Coach:</i> TIAA-CREF Professional Cycling Team 1 st place, Under 23 National Road Cycling Championships 1 st place, Under 23 National Criterium Cycling Championships 1 st place, US Professional Criterium Championships 3 rd place, US Professional Road Championships 1 st place, Team Pursuit, National Track Championships 1 st place, Points Race, National Track Championships 1 st place, Madison, National Track Championships 1 st place, Individual Pursuit, National Track Championships |
| 2005 | <i>Sports Physiologist & Training Advisor:</i> Floyd Landis, 9 th place in the 2005 Tour de France. |
| 2000-2004 | <i>Personal Coach & Advisor:</i> Michael Barry, 2005 Canadian Olympic Team Member Dede Barry, 2004 US Olympic Team Member, Silver Medalist Colby Pearce, 2004 US Olympic Team Member |

| | |
|-----------|--|
| 1999 | Christian VandeVelde, 2000 US Olympic Team Member Scott Moninger, US Record Holder for Total Career Wins Alex Candelario, Collegiate National Road Champion <i>Director/Coach:</i> Celestial Seasonings Women's Cycling Team 1 st Place, Pan American Time Trial Championships 1 st Place, Pan American Road Race Championships 1 st Place, US National Criterium Championships Top American, First Union World Cup, Philadelphia, PA Top American, World Time Trial Championships Top American, World Road Race Championships |
| 1998 | <i>Director/Coach:</i> Celestial Seasonings Women's Cycling Team. 1 st Place, National Time Trial Championships 1 st Place, Under 23 National Time Trial & Road Championships 1 st Place, 1998 Junior National Criterium, Road, & Time Trial Championships (16-17 yrs) |
| 1997 | <i>Resident Coach:</i> U.S. National Cycling Team U.S. Olympic Training Center, Colorado Springs, Colorado. |
| 1994-1995 | <i>Head Coach:</i> CU Boulder Women's Cycling Team 3rd Place, 1995 Collegiate Nationals |
| 1993-1994 | <i>Head Coach:</i> U.C. Davis Cycling Team 1st Place, 1994 Collegiate Nationals |

Public Appearances and Presentations:

| | |
|-------------------------|---|
| Winter-Spring 2005-2006 | <i>Featured Speaker:</i> Nation wide lecture tour examining the power demands of Floyd Landis during the 2005 Tour De France. Sponsored by the Saris Cycling Group. |
| June 7, 2005 | <i>Slide Presentation:</i> "Physiological vs. physical determinants of uphill vs. level time trial performance." American College of Sports medicine 52 nd Annual Meeting. |
| April, 25 2005 | <i>Guest Speaker:</i> "Redefining road cycling performance from field measurements of power." University of Wisconsin, Madison, Department of Mechanical Engineering. |
| July 12, 1999 | <i>Interview & Feature:</i> "Sport Science & Technology in Cycling." <i>NBC Wide World of Sports</i> , HP Women's Challenge. Pioneered use of a rider mounted telemetry system with Tune Inc., that allowed direct video capture of power output, speed, heart rate, and distance from the bicycle. |
| May 31, 1997 | <i>Poster Presentation:</i> "Exercise Induced Desaturation in Elite Female and Male Cyclists." American College of Sports Medicine 44 th Annual Meeting. |

Other:

| | |
|-------------|---|
| Summer 1996 | Advisor & Guest of the Chinese General Consulate. Games of the XXVI Olympiad, Atlanta 1996. |
|-------------|---|

Dr. Wolfram Meier-Augenstein, CChem, MRSC

Senior Lecturer

Environmental Forensics & Human Health Lab.

Environmental Engineering Research Centre

David Keir Building, 39-123 Stranmillis Road

Queen's University Belfast

BELFAST

BT9 5AG

Tel.: 028 – 9097 4015

Fax: 028 – 9066 3754

e-mail: w.meier-augenstein@qub.ac.uk

Career:

- 01.02.07 to date: Senior Lecturer, Environmental Engineering Research Centre; School of Planning, Architecture & Civil Engineering, Queen's University Belfast
- 01.10.05-31.01.07: Lecturer (B), Environmental Engineering Research Centre; School of Planning, Architecture & Civil Engineering, Queen's University Belfast.
- 01.01.03-30.09.05: Research Officer / Senior Research Fellow, Environmental Engineering Research Centre; Civil Engineering, Queen's University Belfast.
- 01.02.99-31.12.02: Senior Research Fellow, Division of Molecular Physiology, School of Life Sciences; University of Dundee. Radiation Protection Supervisor.
- 01.10.97-31.01.99: Research Fellow / Lecturer (Chemistry), Metabolic Studies Group, Dept of Anatomy & Physiology; University of Dundee, UK.
- 01.10.94-30.09.97: Research Fellow / Hon. Lecturer (Chemistry), Metabolic Studies Group, Dept. of Anatomy & Physiology; University of Dundee, UK.
- 01.02.92-30.09.94: Research Assistant, Metabolic Disorders Screening Lab., Dept. of Paediatric Neurology, University Children's Hospital, University of Heidelberg, Germany.
- 01.06.92-31.08.92: Visiting Scientist at Prof. W. N. Nyhan's Biochemical Genetics Lab., University of California San Diego, USA.
- 01.01.90-30.04.91: Post-Doctoral Fellow, Ecological Biochemistry Group, Dept. of Organic Chemistry, University of Stellenbosch, South Africa.
- 01.09.87-31.12.89: Doctoral Fellow, Natural Compound Chemistry Group, Dept. of Organic Chemistry; Radiation Protection Officer; University of Heidelberg, Germany.

Qualifications:

- PhD (1989), *magna cum laude* (mark 1.0), University of Heidelberg, Germany: Title of Thesis: "A PLMF-1 specific receptor in *Mimosa pudica* L."
- Dipl. Chem. (1987), 'good' (mark 1.9), in Chemistry and Molecular Genetics; University of Heidelberg, Germany; Title of Thesis: "A new synthetic pathway for 4-O-(β -D-glucopyranosyl)gallic acid (PLMF-1)."
- Radiation Protection Officer (cert.) (1987), Nuclear Research Centre Karlsruhe, Germany.

Awards:

- Feodor-Lynen Fellowship awarded by the Alexander-von-Humboldt Stiftung, Bonn, Germany; November 1990.
- Post-Doctoral Fellowship awarded by the Foundation for Research Development, Pretoria, South Africa; January 1990.

Research Interests:

- Study of stable isotope profiles and reaction specific isotopic fractionation factors of (bio-)organic compounds for forensic analysis of source, origin and authenticity.
- Study of biochemical transformation of exogenously and endogenously sourced amino acids into keratin and collagen as well as study of metabolic fate, turnover rates and pathways of incorporation of light and trace elements into human hair, nails and bone for forensic determination of geographic point of origin and geographic movement of living people and human remains.
- Design and development of pathway-specific stable isotope labelled probes for direct measurement of (patho-)physiological and metabolic processes to measure environmental impact on human health and for therapy control.
- Compound specific study of volatile organic compounds in human breath and indoor air to determine their origin and relevance as indicators of exposure and/or disease.
- Stable isotope profiling of airborne organic pollutants and contaminants in the environment to determine their age, distribution and point of origin as well as uptake by and metabolic fate in the human body.

Current Grants / Projects:

- Procter & Gamble funded research project (PI) on "Isotope Fingerprinting of Authentic and Counterfeit Goods for both Brand and Consumer Protection"; \$25,000; March 2007 to February 2008.
- EPSRC Think Crime 4th Call grant (PI) with Dr N NicDaeid (CFS, University of Strathclyde): "Isotope Profiling of Drugs to Combat Serious and Organised Crime"; £107,023; February 2006 to January 2009.
- RSC/EPSRC PhD Studentship; "Multi-dimensional Profiling of Drugs and Fibres"; £60,190; October 2006 to March 2010.
- PhD studentship award made by the Defence Science & Technology Laboratory (dstl), Fort Halstead (UK); £29,393; January 2006 – December 2008.
- Invest NI Proof of Concept grant (PI): "Non-invasive functional screening for reduced liver function and adverse drug effects"; February 2005 to July 2006; £108,010.
- EPSRC Platform grant "Environmental Forensics" as Co-Investigator together with Prof RM Kalin (PI) and Dr T Elliot (Co-I); August 2004 to July 2009; £448,624.

Completed Grants / Research Contracts:

- Research project (PI) for longitudinal variation and validation of my SAFEBT Gastric Emptying Breath Test (pat. pending) in adult patients; Johnson & Johnson PRD; April 2004 to October 2005; £62,000.
- Research project (PI) for patient screening and randomisation using my SAFEBT Gastric Emptying Breath Test (pat. pending) in a multi-centre clinical trial setting; Johnson & Johnson PRD Inc; January 2003 to December 2003; £160,400.
- World Anti-Doping Agency (WADA) joint grant application with Prof. M.J. Rennie (PI) (University of Nottingham): "A novel method to detect endogenous and pharmaceutical androgen administration based on two-dimensional isotopic fingerprinting against an endogenous internal standard"; £116,000 for 1.5 years.
- Co-Investigator on Dr Michael Richards' (University of Bradford) NERC research proposal (EFCHED programme): "The evolution of hominid dietary adaptations linked with environmental changes: extending the record beyond 100,000 years"; £123,220 for 3 years.
- Wellcome Trust Project Grant jointly with Prof. Michael J Rennie (PI) (School of Life Sciences, Dundee) to investigate "New approaches to the study of human collagen metabolism in normal adults and after burn injury in children"; July 2000 to June 2002, £360,841.
- Research grant (PI) in collaboration with Dr John F Dillon (Gastroenterology & Hepatology, Ninewells Hospital and Medical School, Dundee) and Dr Anne Rühl (Gastroenterology, University's Hospital Trust, Heidelberg, Germany) to develop "Stable Isotope Labelled Probes for Non-Invasive Assessment of Physiological Functions in the Human Body"; awarded by the Dietmar-Hopp-Stiftung für Medizinische Forschung und Studien (Germany), February 1999 to January 2002, £356,411.
- Research contract (PI) awarded by Phenome Sciences Inc, MassTrace Group, Woburn, MA (USA), for work on new stable isotope labelled probes to assess gastric emptying by means of a $^{13}\text{CO}_2$ -breath test; January 2001, £10,240.
- Industrial grant (PI) awarded by Europa Scientific Ltd., Crewe, for work on GC/C-IRMS application and instrument development; October 1997 to September 1998, £113,985.

Recent unsuccessful Grants / Research Proposals:

- NERC small grant application: "Linking Dietary and Environmentally Derived Signals in Human Tissues to Life Chronology of Modern Man"; as PI together with Prof SM Black (University of Dundee).
- BBSRC standard grant application: "Linking Isotopic Signals to Geographical Origin of Living People and Human Remains"; as PI together with Profs SM Black (University of Dundee) and MP Richards (University of Bradford); invited for resubmission to NERC as archaeologically focused proposal.

Membership of EPSRC funded Networks

- ❖ Forensic Isotope Ratio Mass Spectrometry Network (FIRMS)
- ❖ International Crime Science Network
- ❖ Geoforensics and Information Management for crime Investigation (GIMI).

Collaborations:

- With Dr Niamh NicDaeid (CFS, University of Strathclyde): "Isotope Profiling of Drugs to Combat Serious and Organised Crime" and "Multi-dimensional Profiling of Drugs and Fibres".
- With Dr Damian McKay (Royal Victoria Hospital, Queen's University Belfast): "Monitoring Ulcerative Colitis and its therapy by means of a non-invasive breath test".
- With Prof Sue Black on the identification and determination of geographic origin of archaeological human remains (Seaman Swan).
- With Prof Kenneth Leung and Prof David Dudgeon (Dept. of Ecology & Biodiversity, The University of Hong Kong): "Are stable carbon isotope ratios of essential and non-essential fatty acids accurate tracers in studies of aquatic food webs?"
- With Dr Lesley Houghton (Neurogastroenterology Unit, Academic Division of Medicine and Surgery, University of Manchester): "Can hypnosis be used to induce nausea and is this associated with delayed gastric emptying?"

Forensic Case Work

- Registered forensic expert advisor with the UK's National Crime & Operations Faculty (now National Centre for Police Excellence).
- An Garda Síochána (Dublin): Murder investigation.
- Durham Constabulary: Unidentified body.
- Lothian & Borders Police: Abandoned baby ('Baby Gary').
- National Crime & Operations Faculty: Murder investigation.
- Police Service Northern Ireland: Two murder investigations and one missing persons (presumed to be murdered).
- Strathclyde Police: One case of unidentified skeletal remains (missing persons / possible foul play).

Consultancy Services

- Consultancy services for Adria Ltd, Strabane, Co. Tyrone; July 2003 – April 2004; £18,964.
- Contract study for Guinness-UDV, Brand Innovation Group; May – October 2002; £83,255.
- Consultancy services for Guinness-UDV, Brand Innovation Group, Bishops Stortford, Hertfordshire; July 2001.
- Consultancy services for Isotope Analytical Services Ltd, Bridge of Don, Aberdeen, UK; May 2001.
- Co-founded ASSIST (Applied Scottish Stable Isotope Technology) as commercial arm of Dundee's stable isotope facility in March 2000. Total value of contract analyses: £4,778.
- Consultancy services for Ricardo Consulting Engineers, Shoreham-on-Sea, West Sussex, UK; January 1999.

Membership of Professional Bodies

- Member of the Royal Society of Chemistry and Chartered Chemist.
- Member of the British Mass Spectrometry Society.
- Member of the UK Alexander-von-Humboldt Association.

Outside Recognition:

- External PhD examiner, University of Oxford (UK), 2004.
- External PhD examiner, Swedish University of Agricultural Sciences, Uppsala / Umea, 2005.
- Key-note presentation at the 4th European Academy of Forensic Sciences Conference (EAFS, 13-16 June 2006, Helsinki).
- Programme chair at the 4th the European Academy of Forensic Sciences Conference (EAFS, 13-16 June 2006, Helsinki).
- Invited contributor to a five day course on "Principles and Practice of Stable Light Isotopes" at the University of Bradford (3 – 7 July 2006).
- Member of programme committee of the 5th international conference on application of isotope techniques to ecological studies (ISOECOL, 13-18 August 2006, Belfast).
- Session chair at the 5th international conference on application of isotope techniques to ecological studies (ISOECOL, 13-18 August 2006, Belfast).

Patents and Patent Applications:

1. W. MEIER-AUGENSTEIN: "Gas Inlet System", *Int. Patent Appl. No. PCT/GB96/03213*; *British Patent Appl. No. 9526508.8*; *Publication No. WO 97/23770*.
2. W. MEIER-AUGENSTEIN, J.A. Cairns and J. Thomson: "Catalytic Conversion Interface", *Int. Patent Appl. No. PCT/GB02/00172*; *British Patent Appl. No. GB0101164.2*; *Publication No. WO 02/057007 A2*.
3. W. MEIER-AUGENSTEIN: "Gastric Emptying Test", *Int. Patent Appl. No. PCT/GB02/00528*; *British Patent Appl. No. GB103097.2*; *Publication No. WO 02/062399 A1*.
4. W. MEIER-AUGENSTEIN: "Liver Function Test", *Int. Patent Appl. No. PCT/GB02/01310*; *British Patent Appl. No. GB106923.6*; *Publication No. WO 02/075320 A2*.
5. J. Thomson and W. MEIER-AUGENSTEIN: "CO₂ / NO_x Sensor", *Int. Patent Appl. No. PCT/GB02/03888*; *British Patent Appl. No. GB0120962.6*; *Publication No. WO 03/021245 A2*.
6. W. MEIER-AUGENSTEIN: "Method of Fabric Odour Detection"; *Int. Patent Appl. No. PCT/GB2004/00145*.
7. W. MEIER-AUGENSTEIN: "Breath Test Phenotyping for Adverse Drug Reactions"; *British Patent Appl. No. GB0621829.1*.

John Kenneth Amory MD, MPH, FACP

Office: University of Washington, Box 356429
1959 NE Pacific St
Seattle, WA 98195
Tel: (206) 616-1727 fax: (206) 616-5365
Email: jamory@u.washington.edu
<http://depts.washington.edu/gim/faculty/amory.htm>

Home: 1227 17th Ave E
Seattle, WA 98112-3316
(206) 324-1784

PERSONAL INFORMATION

Born: April 19, 1967, Vancouver, British Columbia, Canada (US citizen)

Married: October 7, 1995 to Josephine Harris Amory MD (Obstetrics)

Children: William Glendinning Amory, born July 5th, 2002

Thomas Gerard Amory born Feb 1st, 2005

EDUCATION

2004-2006 MPH, University of Washington, Seattle, WA

1989-1994 MD with Thesis, University of California, San Francisco, CA

1985-1989 BA Biology-*Magna cum Laude*, Harvard University, Cambridge, MA

POSTGRADUATE TRAINING

1994-1997 Resident in Internal Medicine, University of California, San Francisco, CA

1992-1993 Research Fellow, National Institutes of Health, Bethesda, MD

FACULTY POSITIONS

2005- Associate Professor of Medicine, University of Washington, Seattle, WA

2001-2005 Assistant Professor of Medicine, University of Washington, Seattle, WA

1997-2001 Acting Instructor of Medicine, University of Washington, Seattle, WA

HOSPITAL POSITIONS

2001- Attending Physician, University of Washington, Seattle, WA

1997-2001 Staff Physician and Director Pre-op clinic, VA-Puget Sound, Seattle, WA

HONORS & AWARDS

| | |
|------|---|
| 2007 | Young Andrologist Award, American Society of Andrology |
| 2006 | Named one of "Seattle's Best Doctors" by <i>Seattle Magazine</i> (Internal Med) |
| 2005 | Endocrine Society International Award for Excellence in Published Clinical Research |
| 2004 | Helen and Phillip Fialkow Scholar, Department of Medicine, University of Washington |
| 2003 | Paul Beeson Award for excellence in Housestaff Instruction, Department of Medicine, University of Washington |
| 2003 | AOA honorary inductee, University of Washington Medical School graduating class of 2003 |
| 2003 | Fellowship, American College of Physicians |
| 1997 | Weingarten Memorial Award for outstanding third-year medicine resident, University of California, San Francisco |
| 1996 | Martin Memorial Award for outstanding second-year medicine resident, University of California, San Francisco |
| 1992 | Dean's Prize for Medical Student Research, UCSF |
| 1990 | Dr. June Colburn Research Fellow, UCSF |
| 1987 | John Harvard Scholar |
| 1985 | National Merit Scholar |

CERTIFICATIONS & LICENSURE

| | |
|--------------|---|
| 1997-present | American Board of Internal Medicine, Board Certified in Internal Medicine (renewed 2007-2017) |
| 1997-present | Washington Medical License |
| 1996-present | DEA License |

PROFESSIONAL ORGANIZATIONS

| | |
|--------------|---|
| 1999-present | The Andrology Society |
| 1997-present | American College of Physicians |
| 2003-present | The Endocrine Society |
| 2003-present | Association of Reproductive Health Professionals (Planned Parenthood) |

TEACHING RESPONSIBILITIES

YEARLY:

1. Six weeks ward attending in general inpatient medicine. Responsible for teaching rounds and overseeing patient management.
2. Multiple lectures to residents on general medicine topics including thyroid disease, nutrition, contraception, reproductive disorders, medication side effects and peripheral vascular disease.
3. Human Biology 565 (2nd year medical student course on human reproduction). Co-course director (with Robert Steiner, PhD). 5 hours of course lectures yearly: "The

Adult Male," "Male Infertility," "Male Contraception," "Population Dynamics,"
"Androgens in the Aging Male."

4. Human Biology 665 (3rd year medical student medical clerkship lecture series). 4 hours of course lectures yearly (Acute Renal Failure)
5. Human Biology 544 (2nd year medical student course on endocrinology). Small group leader "Hypothyroidism" "Adrenal Insufficiency"

EDITORIAL RESPONSIBILITIES

At-large reviewer for *Journal of Clinical Endocrinology and Metabolism*, *Endocrinology*, *Human Reproduction*, *Journal of Andrology*, *Asian Journal of Andrology* and others

NATIONAL RESPONSIBILITIES

| | |
|--------------|--|
| 2004-present | United States Anti-Doping Agency, anti-doping review board |
| 2005-present | Reviewer, Faculty of 1000, Reproductive Physiology |

UNIVERSITY SERVICE

| | |
|--------------|---|
| 2004-present | Medical School Admissions Committee |
| 2004-present | Human Subjects (IRB) Committee A-member |
| 2003 | Residency Selection Committee |
| 2002-2004 | Faculty Senate-member |
| 2001-present | UW Hospital Nutrition Committee (Chair) |

CURRENT RESEARCH FUNDING

1. NIH/NICHD
1K23HD045386, 9/04-9/09
PI: John K. Amory Total costs: \$629,668
Oral Androgen Administration and Function in Man
2. NIH/NICHD
Contraceptive Clinical Trials Network
PI: William J. Bremner
John K. Amory, Co-investigator
Contract #: HHSN27520040337
Safety and Gonadotropin Suppressive Activity of Nestorone Gel and Testosterone Gel in Men 4/05-4/07
Total costs: \$225,866
3. NIH/NICHD
U54 HD42454
Center PI: William J. Bremner 9/02-9/07
Project I PI: William J. Bremner
John K. Amory, Co-investigator
Project I: Hormonal Contraception Total costs: \$9.5 m
In the Male Project I costs:
4. NIH/NICHD

- U54 HD012629-27
Center P.I: Robert Braun
Project V PI: William J. Bremner
John K. Amory, Co-investigator
Project V: Gonadotropin Regulation
Steroidogenesis, spermatogenesis and gene
Expression in man
- 4/06-3/11
Total costs: \$10.6 m
Project V costs: 1.5m
5. University of Washington, Center for Research in
Reproduction and Contraception
PI: John K. Amory
Contraceptive pilot grant: Gonadotropin suppression
with oral testosterone enanthate and finasteride
in man
- 6/06-5/07
Total costs: \$35,000
6. NIH/NICHD
HD-05-040
PI: William J. Bremner
Research Mentor/Program Director: **John K. Amory**
Men's Reproductive Health Research
at the University of Washington/
K12 Training program
- 9/06-9/11
Total costs: 2.2 m

PENDING RESEARCH FUNDING

1. GlaxoSmithKline
TDC106220
PI: John K. Amory
Oral nanomilled testosterone in hypogonadal men
- Dates: 1/07-1/08
Total costs: \$310,821
2. Merriam Pharmaceuticals
PI: John K. Amory
Oral administration of the GnRH antagonist acyline
In normal men
- Dates: 3/07-3/08
Total costs: \$100,000
3. NIH/NICHD
RFA-HD-06-014
Center PI: William J. Bremner
Project I PI: **John K. Amory**
Oral testosterone for male hormonal contraception
- 3/07-2/12
Total costs: 13.5m
Project I costs: 2.2m

COMPLETED RESEARCH FUNDING

1. American Professors of Infection Control.
P.I. John K. Amory
Computer-based prevention of urinary tract infection
- 1/00-1/01
Total costs: \$8,000
2. University of Washington, Center for Research in

- | | |
|--|-----------------------|
| Reproduction and Contraception | 5/04-5/06 |
| PI: John K. Amory | Total costs: \$68,211 |
| Contraceptive Pilot Grant: Glycosphingolipid Inhibition and Spermatogenesis in Men | |
-
- | | |
|---|------------------------|
| 3. Schering Pharmaceuticals | 3/05-8/06 |
| PI: John K. Amory | Total costs: \$150,000 |
| Glycosphingolipid Inhibition and Spermatogenesis in Men | |
-
- | | |
|--------------------------|------------------------|
| 4. GlaxoSmithKline, | 12/04-12/06 |
| PI: John K. Amory | Total costs: \$169,000 |

Bicycling

Floyd's Performance: Stage 1

Flat course makes aerodynamic drag an important factor in outcome for Floyd Landis and others

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Stage 1: Saturday, July 2

Route: Fromentine to Noirmoutier-en-l'Île

Type: Time Trial

Distance: 19 Km

Elevation Gain: 0 feet

Total Feet Climbed: 66 feet (20 meters)

At a Glance:

Stage Placing: 6th

GC Placing: 6th

Time: 00:21:53 (00:01:09 down on Dave Zabriskie)

Estimated Average Power: 443 Watts

Estimated Total Work: 582 Kjoules

Stress to Strain Index: 1.13

Today's stage from Fromentine to Noirmoutier-en-l'Île was a nearly perfectly flat 19 kilometer (11.78 miles) time trial with a strong head and cross wind over much of the course. Because we will not be monitoring Floyd's power output during the time trials, I've estimated, based on Floyd's aerodynamic drag, what we believe his average power output was over today's stage. In addition based on the height and weight of his competitors and a mathematical model developed from their previous time trial results, I've come up with an estimate for the power outputs of the rest of the top 10 (Table 1).

On a flat course the primary variable resisting a cyclist's forward motion is aerodynamic drag or wind resistance. Thus, on today's stage a rider's power output is basically equal to their speed multiplied by aerodynamic resistance. Going fast on today's stage not only required a huge amount of power, but also great aerodynamics. In fact, among professional cyclists, on a perfectly flat course, aerodynamics is probably a stronger determinant of speed than their power output.

For example, at 30 mph, an increase in aerodynamic load of only 100 grams or just under a quarter of a pound can increase the power requirement by 15 Watts. That's equivalent to an extra 5 pounds on a 6 percent grade hill and would result in a 45 second time loss over an hour. In today's time trial, if the aerodynamic drag on Dave Zabriskie increased by 100 grams, he would have lost the time trial by about 20 seconds. That's 0.2 seconds per gram. It's interesting to note, that Dave's aerodynamic drag at his speed was about 185 grams less than Lance Armstrong's. Though Lance probably produced the highest average power output of the day, he lost to Dave by only 2 seconds or about 10 grams of aerodynamic drag. If we assume all the riders went 30 mph, then the actual difference in aerodynamic drag between Dave and Lance works out to be only 83 grams, the difference between Dave and Floyd is 44 grams, and Dave and Vinokourov is 48 grams, with Dave more aerodynamic than all of the riders in the top 10. That aerodynamic drag combined with an incredibly impressive power output won the day for Dave, who is likely to only become a stronger rider in the years to come. For a closer look at the effect of body position and speed on aerodynamic drag and power output see Table 2.

For Floyd, the day went quite well and he is extremely happy with his ride. More importantly, he's ecstatic about Dave's performance. Floyd and Dave share an apartment in Girona, Spain, where they live while in Europe. After Dave returned from the Giro D'Italia, Floyd encouraged him to focus strongly on this opening time trial stage, clearly believing that Dave could easily win. Although, the short time trial is not one of Floyd's specialties, among the potential contenders for the overall, he is currently third behind Lance Armstrong and Alexander Vinokourov. Despite the lost time, this race is still wide open with plenty of hard days ahead.

| | Rider Name | Time min:sec | Speed | | Drag N/V ² | Power Watts | Power W/kg | Work Kj |
|----|----------------------|-----------------|-------|------|--------------------------|----------------|---------------|------------|
| | | | kph | mph | | | | |
| 1 | David Zabriskie | 20:51 | 54.68 | 33.9 | 0.121 | 450 | 6.52 | 626 |
| 2 | Lance Armstrong | 20:53 | 54.59 | 33.8 | 0.123 | 476 | 6.61 | 646 |
| 3 | Alexandre Vinokourov | 21:44 | 52.45 | 32.5 | 0.133 | 455 | 6.32 | 593 |
| 4 | George Hincapie | 21:48 | 52.29 | 32.4 | 0.138 | 473 | 5.93 | 663 |
| 5 | Laszlo Bodrogi | 21:50 | 52.21 | 32.4 | 0.124 | 422 | 6.03 | 593 |
| 6 | Floyd Landis | 21:53 | 52.09 | 32.3 | 0.122 | 414 | 6.08 | 582 |
| 7 | Fabian Cancellara | 21:54 | 52.05 | 32.3 | 0.135 | 455 | 5.83 | 641 |
| 8 | Jens Voight | 21:55 | 52.02 | 32.2 | 0.125 | 421 | 6.01 | 593 |
| 9 | Vladimir Karpets | 21:58 | 51.90 | 32.2 | 0.138 | 461 | 5.84 | 651 |
| 10 | Igor Gonzalez | 21:59 | 51.86 | 32.2 | 0.133 | 445 | 5.80 | 650 |

Table 1. Estimated power outputs, power to weights, and total work done for today's top ten calculated from the finishing time and an estimate of aerodynamic drag (Drag in Newtons per velocity squared adjusted for wind speed) based on each rider's height, weight, and a mathematical model developed from previous time trial finishes.

Floyd's Performance: Stage 2

Learn how Landis' stress to strain index is keeping him right on target

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Challans to Les Essarts
Type: Flat Road Race
Distance: 181.5 km
Elevation Gain: 115 meters or 377 feet
Total Feet Climbed: 66 feet or 20 meters

At a Glance:

Stage Placing: 113th
GC Placing: 6th
Time: 03:51:05 (00:00:05 down on Tom Boonen)
Average Power: 206 Watts
Total Work: 2885 Kjoules
Stress to Strain Index: 0.97

Stimulus vs. Response:

With a gain of only 115 meters over 181.5 kilometers or an average percent grade of 0.06%, today's stage was definitely flat, with only minor rollers over the last 30 kilometers. And so it was a day for the sprinters allowing the major GC riders like Floyd to sit in and conserve as much energy as possible.

This year, there's a new rule at the Tour for these flat stages. The finishing time is taken 3 km from the finish so that the riders who don't want to risk fighting it out in a field sprint can sit back and let the sprinters go. For Floyd, this meant that he could relax and hang in the back through the small and twisty roads approaching the finish. With more and more traffic circles dotting the landscape of France it's getting harder and harder for Tour organizers to find a straight and safe line into the small towns where many of the stages finish. The new rule helps to alleviate some of the danger and allows riders like Floyd to focus on two things during these opening stages - conserve and stay out of trouble.

Based on today's power data (**Table 1**), Floyd did a great job of conserving. With an average power output of only 206 watts and a total workload of just 2885 Kjoules, today's race was significantly easier for Floyd than any 4 hour training ride that he'd do alone.

On a rating of perceived exertion scale of 1 to 10 (**Table 2**) Floyd gave the day a 4. We use this rating to determine the stress to strain index listed above which is a simple way to gauge how he's holding up during training and racing. The index is derived from previous testing we have done that describes the relationship between his perceived exertion and his power output when he's fresh and in form. Thus, we use the rating to get a prediction of what he thought or felt his average power was for the day. For Floyd, a rating of 4 gives us a prediction of 200 Watts, which is only 6 watts lower than his actual power of 206 Watts. Since the average power multiplied by time gives us the total work done or energy used, we can also take Floyd's estimated power of 200 Watts and calculate how much work or energy he felt he used - a prediction of 2772 Kjoules or 113 Kjoules less than what he actually did. The index is just the ratio between what he felt his power output or work was and what his actual power output or work was.

©Allen Lim

This distinction between what Floyd actually did versus what he felt he did is an extremely important one. It's what many physiologists term a "Stimulus" vs. "Response" or "Stress" vs. "Strain" relationship. In Floyd's case there's what really happened as measured by the PowerTap ("Cause") and then there's what he thinks happened based on his own perception and feel ("Effect"). To really understand a training or race situation you need to know both.

On a rating of perceived exertion scale of 1 to 10 Floyd gave the day a 4. We use this rating to determine the stress to strain index listed above which is a simple way to gauge how he's holding up during training and racing. The index is derived from previous testing we have done that describes the relationship between his perceived exertion and his power output when he's fresh and in form. Thus, we use the rating to get a prediction of what he thought or felt his average power was for the day. For Floyd, a rating of 4 gives us a prediction of 200 Watts, which is only 6 watts lower than his actual power of 206 Watts. Since the average power multiplied by time gives us the total work done or energy used, we can also take Floyd's estimated power of 200 Watts and calculate how much work or energy he felt he used - a prediction of 2772 Kjoules or 113 Kjoules less than what he actually did. The index is just the ratio between what he felt his power output or work was and what his actual power output or work was.

This distinction between what Floyd actually did versus what he felt he did is an extremely important one. It's what many physiologists term a "Stimulus" vs. "Response" or "Stress" vs. "Strain" relationship. In Floyd's case there's what really happened as measured by the PowerTap ("Cause") and then there's what he thinks happened based on his own perception and feel ("Effect"). To really understand a training or race situation you need to know both.

Table 2. A modified Borg perceived exertion scale used to get a quantifiable number attached to an athlete's subjective rating of how they felt during a given training ride or race. Because the scale is simply an intensity scale and since the total work done or energy expended is equal to intensity multiplied by time, an easy way to get a relative measure of how hard you worked on a given day is to multiply your exercise time in minutes by your perception of effort on a 1 to 10 scale.

As an example, on one day you

GDC00793

Table 1. Floyd's power summary for Stage 2. Based on today's numbers, Floyd had a relatively easy day on the bicycle. His average power output and work are well below his training averages for the duration. His stress to strain index is just below 1.0. Peak power outputs are all lower than his personal bests and training averages. Finally, he distributed the majority of his time below his lactate threshold (an intensity he considers "hard"). In fact, over the course of today's ride, he spent 16.1% or 37 minutes not even pedalling.

| | Stage 2 7/23/05 | Tour de France Average (excluding TT's) |
|-----------------------------|-----------------------|--|
| Duration | 3:51:36 (hrs:min:sec) | 3:52 ± 00.00 (hrs:min) |
| Distance | 181.5 Km or 113 miles | 113 ± 0 miles |
| Average Speed | 29.2 mph | 29.2 ± 0 mph |
| Perception of Effort (1-10) | 4 | 4 ± 0 |
| Average Power | 206 Watts | 206 ± 0 Watts |
| Total Work from Power | 2885 Kjoules | 2885 ± 0 Kjoules |
| Total Work from RPE | 2772 Kjoules | 2772 ± 0 Kjoules |
| Stress to Strain Index | 0.97 | 0.97 ± 0 |
| Peak Power for 5 sec | 830 watts | 830 ± 0 watts |
| Peak Power for 30 sec | 465 watts | 465 ± 0 watts |
| Peak Power for 1 min | 403 watts | 403 ± 0 watts |
| Peak Power for 5 min | 308 watts | 308 ± 0 watts |
| Peak Power for 30 min | 283 watts | 283 ± 0 watts |
| Peak Power for 1 hour | 231 watts | 231 ± 0 watts |
| Peak Power for 2 hours | 214 watts | 214 ± 0 watts |
| Time at Zero Watts | 16.1% or 37 min | 16.1 ± 0% or 37 ± 0 min |
| Time in Recovery Zone | 51.7% or 73 min | 51.7 ± 0% or 73 ± 0 min |
| Time in Endurance Zone | 31.0% or 72 min | 31.0 ± 0% or 72 ± 0 min |
| Time in L.T. Zone | 7.3% or 17 min | 7.3 ± 0% or 17 ± 0 min |

know he's doing what he's suppose to be doing at this stage of the game. As he fatigues and we start to approach the really difficult stages in the mountains, I suspect that the ratio will increase well above 1 to values close to 2.

While this may seem a little complicated it is just another way to quantify the simple question, "How'd you feel today." After all the sophisticated analysis and technology, it's the first thing every coach, including myself, asks. Over the course of the Tour, I'll talk about more of the variables listed in the table below and share more of the subtle tricks and basic principles we use to help Floyd perform optimally. For now, he's right on target. He's conserving and staying out of trouble. More importantly reality and his perception of reality are right in line.

Dr. Allen Lim is an exercise physiologist and coach with Thrive Health Fitness Medicine (www.thrivehfm.com). He received his doctorate at the University of Colorado at Boulder where his research focused on health and human performance with a specific emphasis on optimizing cycling performance with the use of cycle mounted power meters. Over the last decade, Dr. Lim has helped guide a number of teams and individual cyclists to collegiate, national, world, and Olympic medals. This last year, however, he has focused primarily on advising Floyd Landis (www.floydlandis.com) bringing a unique blend of practical, scientific, and philosophical insight to Floyd's Tour de France preparation.

1-10 RPE Scale

what an athlete actually does should be equal to 1. If that athlete thinks the ride is easier than it actually is the ratio would dip below 1. On the other hand, if an athlete thinks the ride is harder than it actually is, the ratio would be greater than 1. Thus, in addition to tracking the average intensity of each day in Watts and the total energy or work done in Kjoules, we also measure Floyd's Stress to Strain Index. At an index just below 0.97, he's just below what an athlete perceives and

may feel great at an average power of 150 Watts, but on the very next day you may feel terrible at the same power output. Since the power output is the same, there has to be something explaining the difference in perception. That something could include factors like fatigue, dehydration, or differences in the environment. Whatever the cause, being able to track the offset between the actual power and the rider's perception of power can give us important insight into the condition or state of an athlete that we wouldn't normally have with either variable alone. If everything is normal, then the ratio between

Floyd's Performance: Stage 3

Saving Energy: Different Spokes for Different Folks

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: La Chataigneraie to Tours
Type: Flat Road Race
Distance: 212.5 km
Elevation Change: - 33 meters or - 108 feet
Total Feet Climbed: 388 meters or 1,273 feet

At a Glance:

Stage Placing: 131th
GC Placing: 6th
Time: 04:36:09 (Same time as winner Tom Boonen)
Average Power: 226 Watts
Total Work: 3743 Kjoules
Stress to Strain Index: 0.88

It was another day for Tom Boonen who's sprinting form is definitely on. With today's win, his confidence is sure to rise and this won't be the last time we see him cross the line first.

The goal for Floyd today was to try and hold an even lower power output than yesterday. At least, that's what we joked about in the bus this morning. Though it's fun to make it a game, conserving energy in these early stages is serious business and will be a critical factor for tomorrow's team time trial and the mountains next week.

There are a couple of things Floyd tries to do to save energy on these early stages. First and foremost, he is never in the wind. Never. If he needs to move up, he either carves his way through the pack or has his teammates pull him up the side. By drafting in the pack, Floyd can save between 40 to 50% of the energy he would be using if he were in the wind. As an example, in yesterday's stage if Floyd did the race by himself or at the front, his average power would have been 410 Watts vs. the 206 Watts he actually did. For all practical purposes, sitting in yesterday saved Floyd 50%.

Another tactic, though somewhat dangerous, is drifting back on the climbs. That is, Floyd will move to the front of the pack before a slight roller or climb and then over the course of that climb, he'll ease up and let himself drift towards the back. If he times it right, then by the time the pack crests the top of the hill, he'll be towards the rear. While it's not always wise to get caught in the back, soft-pedaling the hills not only saves a lot of energy, it's also easier on the body to ride a steady pace rather than a sporadic one.

On the flat or downhill portions, another factor that Floyd tries to stay conscious of is not pedaling. It may sound silly, but over the course of a race a skilled cyclist can coast 10 to 20% of the time. In a 5-hour road race, not pedaling for 20% of the time is equal to not pedaling for 1 hour of that race. Those periods of recovery can save a tremendous amount of energy helping to cut a significant number of miles out of the legs.

One interesting tactic we've adopted specifically for Floyd and his teammates this year is selecting different wheels for different riders based on their specific role for the day. There are a number of different factors resisting a cyclists' movement. Those factors include gravitational resistance (i.e., hills), aerodynamic resistance (i.e., wind), frictional resistance (i.e., bearings & chain), and inertial resistance (i.e., accelerations). On a flat course like today, the two most important factors to consider are aerodynamic resistance and inertial resistance. Thus, our goal is to choose wheels that cheat the wind and that are easy to accelerate. While being more aerodynamic makes intuitive sense, what many people don't realize is that in the middle of a moving pack, where aerodynamics is not as large of a factor, a rider will surge thousands of times, literally between every other pedal stroke, in order to maintain position - mere inches away from the wheel in front. The question at hand is how do we optimize the energy savings for the riders who's job it is to protect Floyd, for Robbie Hunter—the team's sprinter, and of course for Floyd.

To that end, the team is lucky enough to be sponsored by Zipp— a U.S. wheel manufacturer that has not only provided one set of wheels to the team but five different types of wheels, each with different rim depths and weights that allows us to minimize the power cost for each rider.

For Robbie, his goal is to go as fast as possible in the final sprint. Because aerodynamic resistance increases exponentially with speed and since Robbie's job is to go the fastest, he rides the 808 wheel set, which with the deepest depth rim is the most aerodynamic. For the riders protecting Floyd, they need a wheel that is light to help them with the accelerations and aerodynamic since they're in the wind more than Floyd. To that end, they ride the 404 wheel set that is lighter than the 808 but not as deep and thus slightly less aerodynamic.

Finally, because Floyd is so well protected, the aerodynamics of his wheels are not as important as the other riders. What matters more is saving energy by minimizing the cost of the accelerations he makes in the pack. Accordingly, Floyd rides the 202 wheel set that are some of the lightest wheels on the market. Though they are not as aerodynamic as the 808's or 404's, they are still significantly more aerodynamic than a standard 32 spoke wheel (Table 1 & Table 2). In the end, it's about balancing aerodynamic resistance with inertial resistance. Since no single rider has the same role on the team, they each use a wheel set that suits their specific needs.

Table 1. The power required to go 30 mph using a standard 32 spoke wheel versus various Phonak Team Zipp wheels at different wind angles.

Table 2. The power savings at a given wind angle between the Phonak Team Zipp wheels and a standard 32 spoke wheel.

Our hope is that these subtle tactics will help give Floyd and his entire team an edge in tomorrow's team time trial as well as the rest of the race. It's a long haul to Paris, and every bullet saved now could

be a bullet that saves their lives later.

Based on Floyd's power data (Table 3), he had what could be considered another easy day on the bike today. He didn't achieve the goal of riding a lower average power output but it would've been hard with the extra rollers in today's stage. Those rollers and the fact that he didn't spend as much time not pedaling raised his average power. Also, the last hour of today's stage was especially fast and he had to bring it up a notch over the last hour, which not only increased his average power but also caused him to accumulate a bit more time at lactate threshold and above. On the other hand, his stress to strain index was lower today than it was yesterday. A good sign he feels good and is ready to go.

Table 3. Floyd's power data from stage 3 as well as the Tour average and the current minimum and maximum for the last two days.

| | | Stage 3 | Tour Average | Min | Max |
|-------------------|------------------------------|-------------|------------------------|-------------|-------------|

Floyd's Performance: Stage 4

Powerfeed: Landis' team lays it on the line

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Tours to Blois

Type: Team Time Trial

Distance: 67.5 km

Elevation Change: 29 meter gain or 93 feet gain (Average grade = 0.04%)

Total Feet Climbed: 124 meters or 407 feet

Weather: 75° F with overcast skies & cooling off. Perfect riding conditions.

At a Glance:

Stage Placing: 5th

GC Placing: 20th

Time: 01:12:10 (1:31 down on Discovery)

Estimated Average Power for Floyd Pulling: 557 Watts for 1 minute (14.4 min total)

Estimated Average Power for Floyd Drafting: 334 Watts for 4 minutes (57.7 min total)

Overall Estimated Average Power: 379 Watts

Total Work: 1641 Kjoules

Stress to Strain Index: 1.32

It wasn't a bad ride for the Phonak boys, but as team time trial specialists, they had high expectations. While they might be somewhat disappointed, it was still a solid performance—one that required a combination of tremendous power and skill.

Team Time Trial Strategy:

This afternoon, before the race, the boys got together at lunch to do some last minute review of their team trial strategy. Long story short, the tactic was to lay it on the line and go fast. There are a couple of key rules that the team uses in that pursuit. Despite the aggression and brute power required for the team time trial, they all revolve around cooperation and letting go of ego. The basic rules are as follows:

1. Maintain a Constant Speed: A key to keeping things moving and obtaining the fastest speed on a course like today is to try and maintain the most even speed or pace possible. That is, the rider taking a pull will do his best not to try and accelerate or decelerate when he's pulling. Sudden surges within the line can really hurt the riders in the back. At the same time, any drop in speed can really hurt performance. So how do different riders maintain the same speed as the rider before them if there are different ability levels on the team? That brings us to rule 2.

2. Pull Only as Long as You Can Hold the Speed: Since the goal is to maintain an even pace, the weaker riders may only pull for short periods of time (5 to 30 seconds) while the stronger riders will pull for longer periods of time (30 seconds to 1 minute). On average a rider will only pull at the front for about 30 seconds before falling to the back to recover. It takes really knowing yourself and letting go of your pride to ride within yourself and not pull for too long. In the end, if a rider isn't honest with their efforts and blows, that's one less person in the rotation to help provide draft for the others to recover. It's a delicate balance as every rider needs to tow the line between giving an all out effort at the front while still having enough to get back on and recover. If a rider is feeling tired, they will simply move through the rotation and pull off when they reach the front. It's still faster than if that rider wasn't there. It also allows that rider to recover and contribute later in the race. Of course, the ultimate question is, who determines the speed? That brings us to rule 3.

3. Stagger Strong Riders Between Weaker Riders: On the Phonak squad riders like Santiago Botero, Robbie Hunter, Oscar Pereiro, and Floyd are the real strong men in the team time trial. Their experience and strength are used to help keep the pace high and on course. Thus, these riders are staggered between the weaker ones so that at any given point in the rotation there is a minimal amount of time between any modulations in pace. If this wasn't done and there are clusters of strong or weak riders in the line, then there would be periods of time where the pace would be too high and other periods where the pace was too low. The best team time trial riders, not only have the strength to lift the speed should it drop, but also have the skill to do it over a longer period of time, thus helping to keep accelerations in the line at a minimum. Of course, none of this would work without the last and most important rule.

4. Communicate: This is a no brainer, but when the pace is high and riders are on the edge it's hard to remember to let others know how you're feeling or to tell a rider in front if they're going too fast or too slow. From a practical perspective, there's also the need to make sure those in back know what's coming up front. What might be a common courtesy of pointing out a pothole or bump in the road on a weekend ride could be a matter of keeping the train on the tracks or derailing the entire caboose. Although the riders all know each other well and have an intuitive sense of how everyone is doing, that's the direct result of continued and constant communication.

Predicting the Days' Results:

Based on today's course profile, the team's strategy, and their finishing time, I built a mathematical model predicting how much power the average rider had to produce at the front of the line compared to what they were doing when drafting.

At the front of the Phonak line today, the average predicted power to maintain a speed of 56.1 km/hr was 557 watts. For most of the riders that's 130% of the power associated with their maximal ability to consume oxygen or VO2 max. This means, that there's no way that any of the riders could have pulled for more than 4 minutes, which is the average length of time an athlete can ride at their VO2 max. More importantly, this also means that when taking a pull at the front, they are relying heavily on energy from both aerobic and anaerobic sources. Thus, the team trial is one that requires a unique combination of both aerobic and anaerobic capacity.

While sitting in and drafting, I estimated an average power output of 334 Watts. This is about 80% of the athlete's VO2 max, which is just below their lactate threshold (LT) or an intensity they can hold for 1 to 2 hours (More about lactate threshold and VO2 max in future articles). With 8 guys pulling for an average of only 30 seconds, however, there are only 4 minutes just below LT to recover from what is essentially an all out effort.

Thus, even though the weighted average power that I've predicted is only 379 Watts for Floyd (an intensity that is lower than what he'll hold alone in an individual time trial), the team trial is an extraordinarily difficult event because of the hard surges required at the front. It's like an hour of all out interval work with barely enough time to recover. This explains why, his stress to strain index for today is significantly elevated for today's short ride at a value of 1.33.

I also couldn't help but figure what the boys needed to do today to match Discovery's impressive ride. Assuming that the overall aerodynamic drag characteristics and weight of both teams is equal, then each rider on Phonak needed to produce 5.8% more power or 32 more watts at the front and rear to match the winning time. Thus,

each of the Discovery riders had to be redlining at an average power output just below 400 watts for the one-hour duration. An effort like that is at the edge of what's humanely possible. It's an effort that I'm know Team Phonak will have their eyes on for next year.

Floyd's Performance: Stage 5

Determining Landis' Power

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Chambord to Montargis
Type: Flat Road Race
Distance: 183 km
Elevation Change: 20 meter gain or 66 feet gain (Average grade = 0.01%)
Total Feet Climbed: 307 meters or 1007 feet
Weather: 72°F. Cool and overcast with intermittent sprinkles.

Climbs:

1. Cote de Bellevue (Category 4: 1 km at 4.2%)

At a Glance:

Stage Placing: 105th
GC Placing: 20th
Time: 03:46:00 (Same time as winner Robbie McEwan)
Average Power: 220 Watts
Total Work: 2983 Kjoules
Stress to Strain Index: 1.14

Predicted Average Power at Front: 476 Watts
% Savings due to Drafting: 54%

Recap:

Before I get into today's stage, I thought I'd recap a little bit for stage 3 and 4. On stage 3 our goal was for Floyd to try and conserve even more than he did the day before. But by the end of the day he actually had a higher average power. Besides the more undulating terrain, another major factor to that higher average was a strong tailwind that pushed the peloton for most of the day.

Although we normally associate a tailwind with an easier ride, that's really only true for the person in the wind. For someone who is drafting, two things happen. First, the overall speed for any section of terrain is higher so the power required even when drafting is slightly higher. Second, the relative advantage of the draft is decreased. For these reasons, it is actually a little harder to sit in the pack. Primarily, you simply can't soft pedal as much. This was definitely reflected in the 16% time at zero watts on stage 2 vs. the 10.5% time at zero watts on the tailwind aided (or hampered) stage 3.

As for yesterday's team time trial—the good news is Floyd felt great during the race and I think he'll have excellent form in the mountains. The bad news is that the team broke almost every rule in team time trialing—and that's really the nature of the beast. It is such a delicate balance, that one mistake and the day is done. Yesterday, some of the boys were just a little too ambitious and bit off a little more than they could chew. Once that happens, there's no recovering. I think the big lesson learned, and reinforced, is that beyond trying to hold a constant speed, each rider needs to pull off the front before they're blown. For pros, that's sometimes hard to do. And that's exactly why time trialing—especially the team time trial—is an egoless event where pacing and patience are all important.

Stage 5:

From Floyd's perspective, there's not too much to report from today's stage. It was just another day of sitting and hiding in the pack and based on the power analysis (**Table 1**), things are fairly similar to the previous flat stages. In many ways, however, these flat stages are a whole new experience for him.

During his days with U.S. Postal, he spent most of these early days taking 1 to 5 minute pulls in the wind at an average of 400 Watts per pull. Those pulls are 50% more than what he's doing now in the pack. But what does riding at 400 Watts vs. 200 Watts actually mean for Floyd's body? To answer that question, we periodically test Floyd either in the lab or in the field to assess the specific physiological factors determining Floyd's ability to produce power. These same tests are also available to the general public through **Thrive Health**

Fitness Medicine

Determinants of Power:

There are 4 key factors determining a cyclist's ability to produce power. Those factors are:

1. **VO2 max:** An athlete's maximal capacity to consume oxygen.
2. **Lactate Threshold or LT:** The percentage of that maximal capacity that an athlete can hold for an extended period of time (1 to 2 hours).
3. **Efficiency:** the percent of each calorie burned that actually gets transferred to the bike
4. **Anaerobic Capacity or Power:** The maximal amount of power or energy a person can produce in a 5 second to 30 second period of time.

An athlete's VO2 max is the upper limit for how much oxygen they can consume. Since oxygen consumed by your body is directly related to how much energy you're using, VO2 max is essentially the upper limit for how much energy or power your body can generate. VO2 max for a cyclist is what maximal horsepower is for a racecar. In practical terms, an athlete's VO2 max is basically the highest power he or she can hold for about a 4-minute period of time. For Floyd, his power at VO2 max hovers between 450 and 475 watts depending on how fit or tired he is. So, if Floyd were to have taken a turn at the front today, he would've been at 476 Watts or 100% of his VO2 max. While a pull at that power output for less than 4 minutes is well within his capacity, any longer and there might be a serious detonation. That's why when you watch the guys at the front they're rarely pulling for longer than 4 minutes at a time. That's because for most of them they're close to red line when in the wind. Though everyone wants that racecar with the highest maximal horsepower, like max horsepower, VO2 max, while an important factor in an athlete's success, is by no means a make or break factor. It may be a big distinguisher between the average Tour rider and the average guy on the street. Amongst top pros, however, VO2 max is actually a poor predictor of performance.

Because VO2 max and LT are critical physiological attributes, we use them as a reference points for analyzing all of Floyd's power data (**Figure 1**). In the daily power table under "Zone Distribution" you'll notice that we break up the amount of time he spends in different intensity ranges. The first range or "zone" is simply time not pedaling. The second is what we call a "recovery zone," which is the range between zero watts and half the distance to the beginning of Floyd's LT. The "endurance zone" is just the range between the top of recovery to the beginning of LT. The "LT zone" is the power range associated with Floyd's LT. The "race pace zone" is the range between LT and VO2 max. The "VO2 max" zone is the power that elicits Floyd's top end. And finally, "Supra-Max" is anything above his VO2 max. For now, our goal is to accumulate more time in the lower zones. By the time we get into the mountains there will be a significant shift the other way.

©Allen Lim

Although not as large of a determinant of performance as VO2 max and LT amongst professional cyclists, "efficiency" is still an important factor. If you've ever touched the hood of a car after driving or gotten way too hot while exercising then you've just experienced what efficiency or inefficiency is. The reason why we and your car engine gets hot is because most of the energy human and mechanical engines burn is wasted and lost as heat rather than converted to useful mechanical energy. The average cyclist is only 22% efficient on a bike. That means for every 100 Calories they burn while exercising only 22 of those Calories actually goes to the pedals to help move the bike. Some studies have shown that cyclists in the Tour de France can be as much as 27% efficient, while others studies have shown that untrained individuals can be as low as 18% efficient. This number ultimately translates to how much food they need to keep them going (more specifically on food intake during the Tour soon). The more efficient, the less food a rider needs. During the long stages of the Tour where running out of energy and bonking is a real threat, it's the more efficient rider who will have more energy reserves for the end. The last factor determining a cyclist's ability to produce power is their "Anaerobic Power or Capacity." This is how much power they can produce for very short periods of time like a sprint. You might notice that for Floyd, the highest power he's reached so far in the Tour for a 5 second period is 935 watts. In the realm of anaerobic power, that value sucks. As a reference, Robbie McEwen was probably in the 1400 to 1700 watt range in the sprint he won today. Needless to say, Floyd wasn't up there. And that's what is so interesting about the variation in physiology we have at the Tour. For guys like Floyd who possess a high LT, their anaerobic capacity tends to be terrible. Likewise, for the sprinters who have an amazing anaerobic capacity their LT values tend to barely get them over the hills. The one exception is probably Lance, who can climb with the best and sprint if pushed. In coming stages, continue to expect low 5-second peak power values from Floyd as well as higher and higher 30-minute and 1-hour power values from him when he reaches the mountains.

Table 1. Power data for Stage 5. All Tour average statistics as well as min and max values exclude time trial data. Looks like another flat stage.

| | Stage 5 | Tour Average | Min | Max |
|-------------------|------------------------------|--------------|--------------------|-------------|
| Basic Stats | Duration (hr:min) | 3:46 | 4:04 (S5) | 4:30 (S3) |
| | Distance (miles) | 113 | 119 (S1) | 132 (S3) |
| | Average Speed (mph) | 30.1 | 29.3 (S5) | 30.1 (S5) |
| | Perception of Effort (1-10) | 4.5 | 4.3 (S6) | 4.5 (S5) |
| | Average Cadence (RPM) | 86 | 88 (S2) | 90 (S2) |
| | Average Power (Watts) | 220 | 217 (S1) | 220 (S3) |
| | Work from Power (KJoules) | 2983 | 3194 (S4) | 3243 (S3) |
| | Work from RPE (KJoules) | 3390 | 3042 (S2) | 3390 (S5) |
| Peak Power | Stress to Strain Index | 1.54 | 1.00 (S1) | 1.34 (S5) |

Bicycling

Powerfeed: Taking It Nice And Easy Into The Mountains

Floyd remains physically and mentally on track despite weather conditions

By Allen Lim PhD

Stage 6:

Route: Troyes to Nancy
Type: Flat to Rolling Road Race
Distance: 199 km
Elevation Change: 93 meter or 300 feet gain (Average grade = 0.05%)
Total Feet Climbed: 824 meters or 2,704 feet
Average Elevation: 240 ± 88 meters of 788 ± 288 feet above sea level
Minimum Elevation: 111 meters or 364 feet
Maximum Elevation: 398 meters or 1,306 feet/
Weather: 55 to 60°F. Cold, rainy, dangerous and dirty.

Climbs:

1. Cote de Joinville (Cat 4): 1.2 km at 4.5% at 79 km.
2. Cote de Brouthieres (Cat 4): 1.8 km at 4.8% at 102.2 km.
3. Cote de Montigny(Cat 4): 1.4 km at 5.2% at 139.6 km.
4. Cote de Maron (Cat 4): 3.2 km at 5.2% at 182.3 km.

At a Glance:

Stage Placing: 42th
GC Placing: 20th
Time: 04:12:52 (Same time as winner Lorenzo Bernucci)
Average Speed: 47.2 km/hr or 29.4 mph
Average Power: 233 Watts
Total Work: 3523 Kjoules or almost exactly 3523 Kcals burned for Floyd
Stress to Strain Index: 1.07

Predicted Average Power at Front: 444 Watts
% Savings due to Drafting: 52%

Slip and Slide:

Today's stage started out dry and overcast but ended cold, wet and dirty. Of course, in conditions like today there are bound to be crashes. As I was driving through the tight and narrow roads on the course today, I was glad that I wasn't out there riding. Luckily, all the Phonak riders avoided the crash and outside of Floyd getting a flat tire about halfway through the race, the day was actually pretty uneventful. Overall, Floyd thought the conditions made the race a little more difficult but still rated it a 5 on a 1-10 perceived exertion scale. Today might have been the highest average power output (233 watts) of the road stages so far, but it was still only a moderate effort. It looks like we are ramping in nice and easy into the mountains and so far Floyd is physically and mentally right on track.

Calculating Energy Expenditure while Racing:

Part of keeping on track during these early stages and throughout the Tour is proper nutrition and consuming enough calories to maintain weight and energy. This is where the CycleOps Power Tap and our ability to directly measure the actual power output throughout the race brings us a tremendous level of precision and insight.

You might notice that amongst all of the power data, I report how much work is done in a unit called Kjoules. Today's ride was 3,523 Kjoules. Like a Calorie or Kilocalorie, a Kjoule is just another way to represent energy. Because it takes energy to do things different things like riding a bicycle or heating a house, there are also different ways to represent or measure energy. The most common way to measure energy is thermally as the amount of heat something gives off when it's burning. That's how we measure how much energy is in food. Someone literally puts that donut in a pressurized chamber, blows it up, and then measures how much heat it gives off with a thermometer. A calorie is just the amount of heat it takes to raise the temperature of 1 gram of water 1 degree Celsius. So when they say that donut has way too many calories, they know what they're talking about.

Another way to represent energy is mechanically as the amount of force resisting movement over a certain distance. If you've ever tried moving furniture, then you've got a good picture of mechanical work and energy. In the same way that a thermometer measures thermal energy, the CycleOps Power Tap measures mechanical energy. The basic question, however, is this: What's the relationship between Kjoules and Kcals? In other words, how many donuts do I have to burn to move all that furniture or pedal my bike?

Calculating Energy Expenditure while Racing:

Part of keeping on track during these early stages and throughout the Tour is proper nutrition and consuming enough calories to maintain weight and energy. This is where the CycleOps Power Tap and our ability to directly measure the actual power output throughout the race brings us a tremendous level of precision and insight.

You might notice that amongst all of the power data, I report how much work is done in a unit called Kjoules. Today's ride was 3,523 Kjoules. Like a Calorie or Kilocalorie, a Kjoule is just another way to represent energy. Because it takes energy to do things different things like riding a bicycle or heating a house, there are also different ways to represent or measure energy. The most common way to measure energy is thermally as the amount of heat something gives off when it's burning. That's how we measure how much energy is in food. Someone literally puts that donut in a pressurized chamber, blows it up, and then measures how much heat it gives off with a thermometer. A calorie is just the amount of heat it takes to raise the temperature of 1 gram of water 1 degree Celsius. So when they say that donut has way too many calories, they know what they're talking about.

Another way to represent energy is mechanically as the amount of force resisting movement over a certain distance. If you've ever tried moving furniture, then you've got a good picture of mechanical work and energy. In the same way that a thermometer measures thermal energy, the CycleOps Power Tap measures mechanical energy. The basic question, however, is this: What's the relationship between Kjoules and Kcals? In other words, how many donuts do I have to burn to move all that furniture or pedal my bike?

The simple answer is this. 1 Kcal is equal to roughly 4 Kjoules (4.186). So if you do 1000 Kjoules on the bicycle, you've really transferred about 250 Kcals of energy to the rear hub. But does that mean you've only burned 250 Kcals worth of food? The answer is no. Remember, that in **yesterday's article**, I talked a little bit about how a cyclist's efficiency is an important determinant of their ability to produce power. As a reminder, the average cyclist is only about 22% efficient, meaning for every 100 Calories or Kcals they eat, only 22 of those Kcals gets transferred to make the bike move. The rest mostly gets wasted as excess heat. That means if you burn 1000 Kcals of food while riding a bicycle, only about 220 gets transferred to the hub to make the bicycle move. So by a quirk of nature, 1000 Kjoules measured by the Power Tap is equal to just over 1000 Kcals burned by your body. For an average U.S. pro the conversion of Kjoules to Kcals works out to be about 1.1 Kcals for every Kjoule (Table 2). For Floyd the conversion while he's in peak form at the Tour is equal to exactly 1.0. In today's race, doing 3,523 Kjoules means he burned 3,523 Kcals. And this is where the fun begins--getting all those calories replaced so that he can do it all again tomorrow.

Fast Food: For Here and To Go

Everyone always asks me what these guys do in their spare time. Two answers: Eat and Sleep. In addition, to the 3,500 Kcals that Floyd burned in today's race, he also has to consume calories to maintain his already high resting metabolic rate. Those extra calories work out to be 3,000 to 3,500 Kcals. Adding it up and at the end of the day he'll have consumed about 7000 Kcals or 3 to 4 times more than what a normal person needs to eat. Here's a little breakdown of how all that food goes down.

Breakfast:

Like most people, every rider has the basic foods they always eat. In Floyd's case, it's coffee. Whether he was riding in the Tour or hanging out at home he'll always have lots of coffee. In addition to that coffee, breakfast always starts out with 2 to 3 bowls of cereal topped with some muesli, yogurt, and soy milk. 3 maybe 4 eggs and a big plate of pasta follow that. Breakfast or any large meal is eaten at least 3 hours before the race starts so that there is enough time to digest. Those pre-race meals are also filled with foods that have more protein and complex carbohydrates rather than simple sugars - foods that have what we call a low "glycemic index." That is, they're foods that don't spike their blood sugar too much so that we avoid any sugar highs and lows.

Pre-Race:

The riders will typically have a simple snack just before they race -- maybe an energy bar or a few pastries. They're careful not to eat too much within an hour of the start, otherwise, they have problems with digestion and run the risk of getting a sugar low when the race starts. Once they start riding and warming up, however, they'll almost always drink a whole bottle of energy drink.

Race:

During the race, eating is really difficult. Most of the food eaten on the bicycle is the exact opposite of what's eaten at breakfast. They're high glycemic index foods. Foods that bring their blood sugar up really rapidly like candy bars, gels, sweet pastries, Coke, and of course, lots of carbohydrate/electrolyte drinks similar to Gatorade. Because there isn't much blood going to the gut during hard exercise, the riders will try to eat whenever there's a lull in the race to help digestion. They also get most of their calories in during the bike in liquid form, which is easier to absorb. In fact, by the end of the day, almost 70% of all the carbohydrates they take in will be in simple sugars and liquids. If they tried to eat all those calories in solid form two things would happen. The first is that their stomachs just wouldn't be able to handle all that mass and wouldn't digest it all or they'd lose their appetites and lose weight. The second is that if they did get it all in, they'd produce so much fecal matter they probably wouldn't be able to ride the bike the next day.

In the feedbags that are given to the riders at each feed zone and from the cars, there are 3 Power Gels, 2 candy bars, 1 energy bar, 1 small can of coke, 1 bottle of a carbohydrate/electrolyte drink, and 3 pastries wrapped in aluminum foil. Today Floyd went through two of those bags and had 4 bottles of energy drink. He didn't use any of the gels, and so by our calculations he ate about 1600 Kcals on the bike today or about 400 Kcals an hour. In the longer harder days, eating about 1/3rd to 1/2 of what he burns each hour is our basic strategy to keep him from bonking. That is really hard to do. Not only on your stomach but it's also just physically hard to do. In Floyd's case he's adopted this very interesting technique of simply pouring liquids straight down his throat. He just skips the swallowing process all together. He says that it gives him more time to breathe.

Post Race

This is one of the most important meals of the day if not the most important. Immediately after getting into the bus, the riders clean up and start eating and re-hydrating. Immediately after exercise, muscle is really good at reabsorbing energy from food. This enhanced sensitivity is the highest 30-minutes post exercise and slowly fades within 2 to 3 hours. As a result, the food they eat right after getting off the bikes goes right back into their muscles helping them to refuel more quickly for the next day. The basic strategy is to eat as much as is palatable. Foods will include more carbohydrate/electrolyte drinks with a little added protein powder, a sandwich, some boiled potatoes, pastries, and if possible maybe even a plate of pasta with an egg or two on top and plenty of Parmesan cheese and olive oil. On a day like today where he only burned 3,500 Kcals on the bike it's pretty easy for Floyd to replace all the Kcals he burned on the bike post race, especially since he's eating a lot during the race. However, when we get to the really hard stages where he's likely to burn 5,000 to 6,000 Kcals, replacing all those Kcals immediately after will be tough. One very important tool we use to help is a simple scale. Everywhere the team goes, Freddy Viaene, the head soigneur brings the scale. He has the riders weigh themselves every morning and then immediately after they get off the bikes. After a ride, there is a significant amount of fluid loss that is reflected directly in a loss in weight. In the short term, every kilogram of weight lost is equal to 1 kilogram of fluid that needs to be replaced. In the long term, over the course of the race, all the riders will lose a little bit of weight, but if they lose too much too fast, the scale alerts them and they focus on getting more food in.

Dinner:

By the time dinner comes around, the riders are back to normal food. Except that instead of appetizers, they'll almost always start with two huge plates of pasta with red sauce and Parmesan cheese or olive oil and Parmesan cheese, both normally topped with fried egg whites. Then it's on to an extra large salad. And then finally, they'll have a normal meal, like your average human that will consist of some vegetables, rice or potatoes, and some chicken, fish, or steak.

Overall Breakdown:

6,000 to 10,000 Kcals consumed each day or 30 to 50 Krispy Cr? Donuts.

65% Carbohydrate - Over half coming in simple sugars and in liquid form.

20% Protein - Much of it from protein powder, egg whites, and 1 or two servings of animal meat for a total of 1.5 to 2 grams of protein per kilogram of body weight (Average team rider is 70 kg, so that's about 100 to 140 grams of protein. There are 10 grams of protein in 1 egg.)

15% Fat - Olive oil, animal fat, butter, ice cream, and everything tasty.

Table 1. Floyd's power data for stage 6. Beyond the higher average power output, the data looks fairly similar to the other flat stages, except for a bit more time spent at LT and above intensities. This is probably directly related to the greater climbing, more undulating terrain, and cold weather that likely motivated the riders to keep pressure on the pedals.

Table 2. The conversion of Kjoules to Kcals depends on a person's gross mechanical efficiency (GME) or the percent of food energy a person is able to convert to actual mechanical work. For most individuals GME is equal to 22%. While the table above describes this relationship relative to rider experience, the GME is not necessarily dependent on a rider's experience and can be affected by a number of factors like training state, biomechanics, temperature, and the type of ride (e.g., intervals vs. steady). Thus, the number of Kcals burned for a given

| | Stage 6 | Tour Average | Min | Max |
|------------------------------|-------------|----------------------|-------------|-------------|
| Basic Stats | | | | |
| Burial (hrs:min) | 4:32 | 4:06 ± 0:23 | 3:46 (S3) | 4:36 (S3) |
| Distance (miles) | 123 | 120 ± 9.1 | 113 (S5) | 132 (S3) |
| Average Speed (mph) | 29.4 | 29.3 ± 0.61 | 28.6 (S3) | 30.1 (S5) |
| Perception of Effort (1-10) | 5 | 4.5 ± 0.6 | 4 (S2, S3) | 5 (S6, S7) |
| Average Cadence (RPM) | 81 | 86.5 ± 4 | 81 (S6) | 90 (S2) |

number of Kjoules can vary from a high of 1.33 Kcals per Kjoule to a low of 0.92 Kcals per Kjoule depending on the individual and condition. While the table above describes this relationship relative to rider experience, the GME is not necessarily dependent on a rider's experience and can be affected by a number of factors

| Gross Mechanical Efficiency | Correction Factor Kjoules to Kcals | Rider Experience |
|-----------------------------|------------------------------------|------------------|
| 18% | 1.33 | Novice |
| 19% | 1.26 | |
| 20% | 1.19 | Amateur |
| 21% | 1.14 | |
| 22% | 1.09 | U.S. Pro |
| 23% | 1.04 | |
| 24% | 1.00 | Grand Tour Pro |
| 25% | 0.96 | |
| 26% | 0.92 | |

1 A "Calorie" spelled with a capital "C" is actually equal to 1000 "calories" spelled with a lowercase "c." Likewise, 1 Kilocalorie or Kcal is also equal to 1000 calories. By convention on U.S. food labels 1 Kilocalorie is labeled as 1 Calorie, not as 1000 calories. I

guess the powers that be didn't want us to think we were eating hundreds of thousands of calories each day even though in actuality we are.

Dr. Allen Lim is an exercise physiologist and coach with **Thrive Health Fitness Medicine**. He received his doctorate at the University of Colorado at Boulder where his research focused on health and human performance with a specific emphasis on optimizing cycling performance with the use of cycle mounted power meters. Over the last decade, Dr. Lim has helped guide a number of teams and individual cyclists to collegiate, national, world, and Olympic medals. This last year, however, he has focused primarily on advising **Floyd Landis** bringing a unique blend of practical, scientific, and philosophical insight to Floyd's Tour de France preparation.

Bicycling

Powerfeed: A Week Of Consistency

First week of racing is a mini-taper to the mountains

By Allen Lim PhD

CycleOps

Stage 7: Friday, July 8th

Route: Luneville to Karlsruhe

Type: Mostly flat road race with 1 cat 4 and 1 cat 3 climb

Distance: 228.5 km

Elevation Change: - 114 meter or - 368 feet drop (Average grade = - 0.05%)

Total Feet Climbed: 618 meters or 2,028 feet

Average Elevation: 238 +/- 124 meters or 781 +/- 405 feet above sea level

Minimum Elevation: 118 meters or 387 feet

Maximum Elevation: 637 meters or 2,090 feet

Weather: 57 to 62° F. Cool with sporadic rain

Climbs:

1. Col de la Chipotte (Cat 4): 1.9 km at 4.3% at 45 km.

2. Cote de Brouthieres (Cat 3): 3.5 km at 5.0% at 102.2 km.

At a Glance:

Stage Placing: 85th

GC Placing: 18th

Time: 05:03:45 (Same time as winner Robbie McEwen)

Average Speed: 47.2 km/hr or 29.4 mph

Average Power: 225 Watts

Total Work: 4,101 Kjoules or almost exactly 4,400 Kcals burned for Floyd

Stress to Strain Index:

Predicted Average Power at Front: 395 Watts

% Savings due to Drafting: 44%

Recap: Wet is Good

After every race, I wait for Floyd at the team bus where I get a minute or two to grab the Power Tap computer off the bike and get an assessment of how the day went. Then I'm off to the press center to crunch the numbers and get the power feed sent while Floyd is rushed to the hotel to get cleaned up and recover. That means we don't usually catch up until later in the evening after I've sent the data. So I thought I'd start again by sharing some of Floyd's thoughts from yesterday.

Most of those thoughts had to do with the rain. It may have been a factor for many of the riders yesterday, but for Floyd...well, he actually enjoyed himself. Not that he likes riding in the rain. Just that suffering in the rain is a relative thing and it doesn't bother him as much as it bothers many of the other riders. In particular, on flat cold stages like yesterday and today it's normally the smaller climbing specialists who are most negatively affected.

©Allen Lim

That's because a person's surface area doesn't change proportional with their body weight. A pure climber might be 10 to 20 lbs lighter than the average rider but will only have a slightly smaller surface area. As a result, they tend to get blown around a lot more on the flats. It's like having two almost equally sized kites flying in the wind, with one of them held down by significantly less weight. In addition, the more surface area you have the more area you have to lose body heat. Since the smaller guys have less body mass and produce less absolute power, they don't generate as much heat for a given body area as the larger guys do and end up having a harder time staying warm in the cold and wet rain. When things start going uphill and the temperature rises, however, their smaller body size will be a major advantage since they'll have a better power to weight ratio than the bigger riders and since, relatively speaking, they'll be able to stay a bit cooler. Thus, from our perspective it's probably a good thing that we've got poor weather conditions now during the fast and flat stage because it ends up hurting the small climbers a lot more than it hurts Floyd.

Given that he doesn't mind riding in the rain, I asked Floyd if he had any particular strategies for dealing with the wet weather. Besides just sucking it up and dealing, here are a few he relayed that I thought were interesting.

Remember that in dry conditions, if Floyd is trying to conserve, he'll move to the front at the base of a climb and then drift back over the course of the climb. In wet conditions, Floyd will do the opposite. Instead of drifting back on the climb, he'll actually do a little more work and try and get to the front by the top of the climb. That way when he starts the descent he gets a good view of what's to come. Then over the course of the descent, he'll actually ride slower than the other riders and drift towards the back. Not only is he being conservative, he's also letting riders who are going faster than him run the risk of crashing on any potential oil patches or slick sections of road paint. In a lot of cases, those crashing riders simply point out where the bad sections of road are and with Floyd drifting back he's got more time to react. Essentially, by getting to the top of the climb first, he can ride slower on the descent than others while still keeping in contact with the peloton.

Another trick; he rubs his fingers between his glasses when they get covered in water. The oil on his fingers actually helps to bead the water off the lenses. The effect only lasts for a minute or two, but it's better than not seeing anything for those few minutes. Also, if it's going to rain, he makes sure that he's got a clean or relatively new helmet. If he's wearing an old and dirty helmet, then in the first 5 to 10 minutes of a heavy rain, the accumulated salt in the pads of a dirty helmet will run out and sting the eyes. With a clean helmet, this doesn't happen because there's not that much salt in the pads. Finally, he smiles. When riders get really stressed out in the pack, which is common in the rain, you'll notice that their faces tense up. By actually relaxing his face, he feels that it relaxes the rest of his body and keeps him less tense. Robbie Hunter, Floyd's roommate here at the Tour, however, was quick to point out that if he ever caught Floyd smiling at him in the rain, he'd clobber him.

Into Germany:

With dark clouds over head at the start, I actually felt okay about the possibility of it dumping rain all day. By the end of the day, it actually cleared up and if any of you back home are getting bored of these flat stages, then you'll be upset to learn that the only thing different about Floyd's data today was that the race was longer. That extra length, however, does change a few things. At a similar average power output of 225 watts, a longer duration means Floyd did more work (4,101 Kjoules) and of course burned more Kcals (Just over 4,400 Kcals).

My Bad:

If you've just noticed that today's value for Kcals isn't exactly the same as the number of Kjoules then you actually caught me making a mistake in yesterday's article that Floyd pointed out to me last night. On cold days, we know that Floyd is not quite as efficient. Thus, the conversion of Kjoules to Kcals isn't quite 1 to 1. It's closer to 1 to 1.1, or 10% more than the number of Kjoules done. Floyd also wanted me to point out that while he does eat a lot of food on the bike during the Tour, when he's training and trying to make weight for the Tour he doesn't eat nearly as much. For the average person trying to lose weight by exercising on the bicycle, it's a good reminder that that bottle of Gatorade and Power Bar is probably better left at home.

In any case, today's race was significant only in that Floyd burned more calories today than any other stage to date and that because of the longer duration, he also spent more absolute time in each different intensity zone. Otherwise, we are both really surprised by how consistent these opening flat road stages have been. It's been like the movie Groundhog Day and we're both anxious to either get the girl or get to the mountains.

On Track to Better Training Strategies:

Still, tracking what the first week in the Tour is all about has been truly insightful. It's made us realize that it is possible to use the first week of the Tour as a bit of a mini-taper. Beyond the shear stress of being at this event, Floyd has been able to really conserve and hide. Understanding this first week is also giving us a reference point for how we might design the week leading into hard training periods. In the past, I've found that it's really hard to get an athlete to train all out for more than two weeks at a time before they crack. Thus, it's been hard for me to conceive how someone could get through racing a three-week stage race like the Tour all out. I guess what we're confirming is that it's not possible. Everyday we move along, the power data we collect will become more and more valuable. That's because until you truly understand the actual physical demands of an event, there's no way that you can design a really optimal training program. To that end, tomorrow, I'll take some time and talk about the very basic training principles we use to design Floyd's training and how the power data actually helps bring those basic principles to life.

Table 1. Floyd's power data for stage 7. The major difference between this stage and the previous flat stages was the distance. The riders covered the most distance today giving stage 7 the highest amount of work and most absolute time in different intensity zones. Otherwise, everything else looks exactly like the other stages.

| | Stage 7 | Tour Average | Min | Max |
|-------------------|------------------------------|--------------|----------------------|-------------|
| Basic Stats | Duration (hrs:min) | 5:04 | 4:18 ± 0:12 | 5:46 (S5) |
| | Distance (miles) | 142 | 125 ± 12 | 143 (S5) |
| | Average Speed (mph) | 28 | 29.1 ± 0.8 | 30.1 (S5) |
| | Perception of Effort (1-10) | 4.5 | 4.3 ± 0.5 | 5 (S6, S7) |
| | Average Cadence (RPM) | 88 | 86.8 ± 4 | 90 (S2) |
| | Average Power (Watts) | 225 | 222 ± 10 | 233 (S6) |
| | Work from Power (Kjoules) | 4101 | 3441 ± 520 | 4101 (S7) |
| Peak Power | Work from RPE (Kjoules) | 4101 | 3471 ± 503 | 2772 (S2) |
| | Stress to Strain Index | 1 | 1.01 ± 0.10 | 1.14 (S5) |
| | 5 sec (Watts) | 890 | 842 ± 71 | 760 (S6) |
| | 30 sec (Watts) | 540 | 530 ± 42 | 465 (S2) |
| | 1 min (Watts) | 422 | 439 ± 28 | 403 (S2) |
| | 5 min (Watts) | 356 | 349 ± 30 | 308 (S2) |
| | 30 min (Watts) | 264 | 271 ± 26 | 249 (S2) |
| Zone Distribution | 1 hour (Watts) | 255 | 251 ± 17 | 231 (S2) |
| | 2 hours (Watts) | 235 | 236 ± 8 | 227 (S2) |
| | Zero Watts (% or min) | 13.5% or 41 | 15 ± 2% or 34 ± 5 | 20 min (S3) |
| | Recovery (% or min) | 28.4% or 86 | 29 ± 2% or 75 ± 9 | 65 min (S5) |
| | Endurance (% or min) | 33.0% or 101 | 33 ± 2% or 56 ± 13 | 72 min (S2) |
| | Lactate Threshold (% or min) | 8.2% or 25 | 8 ± 0.6% or 21 ± 3 | 17 min (S2) |
| | Race Pace (% or min) | 6.8% or 21 | 6 ± 0.7% or 15 ± 2.7 | 12 min (S2) |
| Zone Distribution | Max (% or min) | 4.2% or 13 | 4 ± 0.5% or 11 ± 2 | 8 min (S2) |
| | Supra-Max (% or min) | 5.6% or 17 | 5 ± 0.4% or 15 ± 1.9 | 13 min (S2) |

Bicycling

Powerfeed: New Highs

Stage 8: Today's numbers bring us a taste of what's to come

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Pforzheim to Gerardmer

Type: A perfectly flat course sandwiched between 4 category 3 climbs in the first 50 km and 1 category 2 climb at 216 km.

Distance: 231.5 km

Elevation Change: 361 meter or 1,184 feet gain (Average grade = 0.16%)

Total Feet Climbed: 1,912 meters or 6,273 feet

Average Elevation: 317 ± 224 meters of 1045 ± 736 feet above sea level

Minimum Elevation: 137 meters or 449.5 feet

Maximum Elevation: 1139 meters or 3,737 feet

Weather: 55 to 65°F. Cool with sporadic rain once again

Climbs:

1. Cote de Dobel (Cat 3): 5.9 km at 5.9% at 14.5 km.
2. Cote de Bad-Herrenalb (Cat 3): 3.9 km at 4.3% at 27 km.
3. Cote de Nachtigal (Cat 3): 3.8 km at 5.8% at 38.5 km.
4. Cote de Zimmerplatz (Cat 3): 1.9 km at 6.7% at 48 km.
5. Col de la Schlucht (Cat 2): 16.8 km at 4.4% at 216 km

At a Glance:

Stage Placing: 27th

GC Placing: 10th

Time: 05:03:54 (27 seconds down on winner Pieter Weening)

Average Speed: 45.7 km/hr or 28.3 mph

Average Power: 255 Watts

Total Work: 4,650 Kjoules

Stress to Strain Index: 1.18

Predicted Average Power at Front: 416 Watts

% Savings due to Drafting: 39%

Stage 7 Recap: Spirits are Good

Almost all the time that I've spent with Floyd has been during really hard training blocks. So when I'm with him, he's usually beat down and tired, while I'm antsy and wanting to go out. But beat down was exactly how I was feeling yesterday after my first freshman week of Tour madness. When I finally caught up with Floyd at the hotel, it was actually the first time I've ever seen him so relaxed and happy. The role reversal was a good one, as it definitely helped to lift my fatigue. Compared to previous Tours Floyd has done, this first week shift is a great surprise for both of us. Consequently, I don't have much to report from Floyd as I basically just lied on the floor while he watched Tour highlights on T.V. bursting out in laughter and amazement every time they replayed a late race crash - a crash that he has no idea how he got through.

Just a Little Taste:

The last climb today caused a decent separation with only 34 riders making the split over the top of the Col de la Schlucht - a category 2 rated climb that began 216 km into the race and lasted 16.8 km with an average grade of 4.4%. Today, it was this climb and a strong tailwind across the flats leading into it that played the most significant role in the race and in the changes in Floyd's power data.

In today's race, the vast majority of the time Floyd spent at or above his lactate threshold (LT) occurred in the last 2 hours. It was a fast and hard lead up to the climb, with Discovery throttling the pace and not gaining too much for it as all of them were dropped on the final climb. While there seems to be a little bit of a buzz about Lance being isolated, based on Floyd's data, I don't think there's any way that Discovery could have worked that hard and not gotten popped.

In fact, you'll notice that today, Floyd achieved his highest peak power outputs for every single time frame in this year's Tour. All of them occurred in the last two hours, with his peak power for 1-minute, 5-minutes, and 30-minutes each occurring on the final climb, which took the riders just over half an hour to get over. Though Floyd only needed to average 376 watts for the Col de la Schlucht - an intensity that is right at the beginning of his LT, his peak 1-minute power of 524 watts occurred right at the beginning of the climb while his peak 5-minute power of 454 watts occurred over the top of the climb. Over the last 10 minutes of the climb, he averaged 435 watts. If this didn't unload a lot of baggage I'm not sure what would. While plenty of guys can handle a hard surge of 454 watts for 5-minutes, very few can handle that after already riding at close to that intensity the 5 minutes before.

These efforts are so much greater than anything we've seen this week, that the kind of split we saw today makes a lot of sense as does the Discovery absence. In the 30 minutes leading up the climb, the pace was the fastest it was all day. Just to sit in during that time period, Floyd had to average 275 watts. Though these new highs for peak power today are significant, they're still below the best Floyd, and I'm sure his competitors, have produced this year. Thus, this first climb was just a little taste of some real exciting racing to come.

You might also notice in today's data (Table 1) that the finishing time was almost exactly the same as yesterday. I thought that was weird. At almost the same average speed with a little more distance and close to 4000 feet more climbing than yesterday, the race today was definitely a notch up on previous days. Likewise, Floyd gave it his highest rating of any road stage so far lifting the day's stress to strain index to 1.18. With a higher average power and just over 5 hours of racing, Floyd burned more calories today (? 4,900 kcals) than any other stage and I'm sure everyone will be taking an extra serving at dinner tonight. Of note, the strong tail wind and fast speed resulted in Floyd spending the least amount of time not pedaling in any stage yet. Only 26 minutes of coasting for the longest stage this week, compared to almost 41 minutes in yesterday's stage.

One last thing I'd like to point out is that in today's race, Floyd rode a total of 1 hour and 48 minutes at or above his lactate threshold. These are intensity ranges that

are highly dependent on carbohydrate. The average professional cyclist can hold anywhere from 1.5 to 2.5 hours worth of carbohydrate in the form of glycogen in their legs. Once a cyclist is out of glycogen, they'll bonk unless they ingest more carbohydrate. Because, carbohydrate is also used at intensities below the lactate threshold, it is absolutely critical that the riders eat plenty of food during stages like today. It's a great reminder to Floyd that even though he's been able to loaf it a bit this week, the days to come will be orders of magnitude more difficult and that right now, the power data is just a strong reminder to stay focused on the basics.

After this race, however, this data will be the most important intelligence we'll have for designing future training programs for the Tour. In that sense, the real reason we're collecting the data here at the Tour is because it's the best investment we can make for tomorrow. The fact is that a power meter doesn't change the essential nature of training, it simply allows us to actually apply the very basic training principles athletes and coaches have been theorizing about for years.

Basic Training Principles Have Not Changed:

Despite all of the sophisticated technology and science at our disposal today, the type of common sense advice that your parents would give you about life when you were a kid are the same for effective training. Listen to yourself, do your homework, everything takes time, if you're tired then rest, and if you're not then get out of the house. Translated in more academic terms, the fundamentals of training are 1) Specificity, 2) Individuality, 3) Progression, and 4) Periodization.

Specificity:

When I was in school, I loved history but hated math. The problem was, doing my history homework and avoiding the math, never helped me in math class. The same is true with training. If you want to be a good bike racer, you need to race bikes. If you want to win the Tour de France, you need to know what happens in the Tour de France and train specifically for those demands.

As terribly fundamental as this concept may be, in endurance sports where intensity has historically been measured with heart rate or perceived exertion, measuring the specific demands of any given event remained an un-definitive often vague process. It was like knowing that the oven needed to be hot to bake a loaf of bread but never being able to actually measure the temperature of the oven. Instead, you'd stick a loaf of dough in and sometimes it'd come out doughy, sometimes burnt, and only occasionally just right. Through continual trial and error and years of experience, a good baker would eventually figure it out, as have generations of athletes. But imagine speeding up that process with simple objective tools.

In that sense, the power meter has done to training what the thermometer has done for baking and the field of science in general. In fact, if you think about it, the thermometer, which simply measures thermal energy, is perhaps one of our most important scientific inventions. It was the one tool that brought us out of the dark ages as almost every chemical and physical process is dependent on knowing temperature. Thus, knowing temperature spawned a golden age of scientific experiments and discoveries.

Like the thermometer, the power meter also measures energy - mechanical energy - the energy of movement - sometimes play, sometimes toil. So instead of guessing how hard it is to drag that suitcase across the room, you can put a number to it. Just like you can put an objective, reliable, and repeatable number to how hot or cold you feel with temperature, measuring power or watts with Floyd allows us to put objective, reliable, and repeatable numbers to how hard or easy each day in the Tour is. By doing so, we know very specific things. We know exactly how hard a finishing climb might be after 4 hours of racing. We know how many calories he burns after a week of hiding in the peleton. We know that the Tour is the hardest race in the entire world. But now we have the specific temperature or wattage that we have to set his training at to make sure he's better prepared than the next guy.

Individuality:

Although we can now definitively quantify the absolute power and energy required to compete in the Tour, it doesn't mean that anyone can just do that training and be ready for the Tour. One of the reasons we feel comfortable about sharing Floyd's power data is because we know it is specific only to Floyd. Two individuals given exactly the same training will not necessarily adapt in exactly the same way. In addition, every individual here in the Tour is experiencing something different and doing something different every day even though they are all racing in the same pack. So it's important to realize that the information we share on Floyd is by no means representative of the entire pack or individuals in that pack.

With this in mind, you can't follow someone else's recipe for training. You need to take the time to develop your own. Because we have power values and ways to represent Floyd's individual training, that individualized process actually takes less time than mimicking another's approach. To that end, you really do have to just listen to yourself and follow your own instincts making as many mistakes as possible along the way. It's those mistakes that will teach you who you are and how your body responds to work. It's a personal process - that's just the way it is.

Progression:

There's an ancient myth about Milon of Crotona, who in 500 B.C. was considered the world's strongest man. As legend has it, he would begin his training each season by lifting a small calf over his head. As the calf grew, so would Milon's strength, until he was able to lift the full-grown cow. It's exactly this slow, incremental, and patient process that is at the heart of training. In practical terms, by knowing what is required at the Tour de France, we can work backwards in time. So let's say for next year Floyd starts serious prep work in January. At the point in time we can measure how much power he's able to produce for different time frames, do some long test rides and examine how much work he can handle, and then from those references we can plot as progressive of a course to what we expect him to do at the Tour. If he doesn't win this year but we know it would've taken an extra 1 or 2 or 3% more on any given day to win, then we advance that progression so he's well prepared for the next year.

This year, he made tiny steps each week, raising his power by 5 or 10 watts during each training block. While it was never a huge jump, it was the fact that we could always measure those numbers and always had goals set for where we wanted them to be. That's progression in the short term.

In the long-term...well, that started for Floyd when he was a 15-year old kid who would sneak out of the house at 9 at night just to ride his bike. The rest, as they say is history.

Periodization:

The last principle is about balance. You might have often heard people use the word "periodization" when they refer to how they or their coach or their personal trainer sets up their training. While it sounds like a sophisticated term, it's not actually a real word. I know, cause I tried looking it up. What it actually refers to is breaking your training up into different periods.

The concept of periodization was first developed by Russian scientists who found that an athlete's fitness could be optimized if their training was divided into distinct periods of time, each isolating a specific physiological variable or skill important to performance. On a basic level, unique combinations of volume, intensity, and technique characterized different periods of the training season. More importantly, there was the idea that an optimal order existed for developing attributes such as endurance, strength, and speed and that each attribute should be emphasized at different periods over the course of a season or athletic career. A final premise of periodization was that the natural highs and lows associated with training and racing could be controlled with the right combination of work and rest to create specifically timed peaks.

Unfortunately, predicting and manipulating natural patterns, in disciplines ranging from biology to economics, has been the bane of scientists and gurus for hundreds of years. Likewise, the scientific literature examining periodization can be as complex and variable as models for predicting the weather. So here's the long story short. If you're tired, then rest. If you're not then you better train as hard as you can until you're tired. Then you can rest again. We applied this simple principle to Floyd before his Tour prep by setting up 2 to 3 week periods of time (usually with a race in the middle) where he would just attempt to bury himself. When he cracked, he'd get really irritable and then he'd sleep for a day. Just like shaking off a bad hangover. So this year our essential philosophy was to structure big picture ideas in his training (climb more, train harder, etc...) and then on any given day just let him do whatever he could handle. The whole time Floyd would really listen to his own body and go by feel, even if it meant that 4 days before the Tour he was canceling his flight and riding to France. Rather than try to plan everything, we took the opposite approach and tracked everything. What occurred was the discovery of a very natural and consistent oscillation that is specific to Floyd. Now that we know what his periodization pattern is, we are we'll armed for planning his hard training and recovery for next year.

Table 1. Floyd's power data for Stage 8. Brand new max values all across the board.

| | Stage 8 | Tour Average | Min | Max |
|-------------------|------------------------------|--------------|----------------------|-------------|
| Basic Stats | Duration (hrs:min) | 5:04 | 4:25 ± 0:35 | 5:46 (S5) |
| | Distance (miles) | 144 | 128 ± 14 | 173 (S5) |
| | Average Speed (mph) | 28.3 | 28.9 ± 0.8 | 28.1 (S7) |
| | Perception of Effort (1-10) | 6 | 4.8 ± 0.5 | 4 (S2, S3) |
| | Average Cadence (RPM) | 87 | 86.8 ± 3 | 81 (S6) |
| | Average Power (Watts) | 255 | 228 ± 16 | 206 (S2) |
| | Work from Power (KJoules) | 4650 | 3642 ± 678 | 2855 (S2) |
| Peak Power | Work from RPE (KJoules) | 5470 | 3504 ± 932 | 2772 (S2) |
| | Stress to Strain Index | 1.18 | 1.04 ± 0.12 | 0.88 (S3) |
| | 5 sec (Watts) | 965 | 862 ± 51 | 760 (S6) |
| | 30 sec (Watts) | 613 | 544 ± 51 | 465 (S2) |
| | 1 min (Watts) | 513 | 451 ± 39 | 403 (S2) |
| | 5 min (Watts) | 354 | 368 ± 40 | 308 (S2) |
| | 30 min (Watts) | 386 | 290 ± 52 | 249 (S2) |
| Zone Distribution | 1 hour (Watts) | 533 | 265 ± 37 | 231 (S2) |
| | 2 hours (Watts) | 264 | 244 ± 21 | 227 (S2) |
| | Zero Watts (% or min) | 8.6% or 26 | 12.4 ± 3% or 33 ± 5 | 26 min (S8) |
| | Recovery (% or min) | 22.5% or 68 | 28 ± 3% or 74 ± 8 | 65 min (S3) |
| | Endurance (% or min) | 33.7% or 102 | 33 ± 2% or 89 ± 14 | 72 min (S2) |
| | Lactate Threshold (% or min) | 10.6% or 32 | 9 ± 1% or 23 ± 5 | 17 min (S2) |
| | Race Pace (% or min) | 9.6% or 29 | 7 ± 1.5% or 19 ± 6 | 12 min (S2) |
| Zone Distribution | Max (% or min) | 7.2% or 22 | 5 ± 1% or 13 ± 5 | 5 min (S2) |
| | Supra-Max (% or min) | 7.8% or 24 | 6.2 ± 0.9% or 17 ± 4 | 13 min (S2) |

Dr. Allen Lim is an exercise physiologist and coach with **Thrive Health Fitness Medicine**. He received his doctorate at the University of Colorado at Boulder where his research focused on health and human performance with a specific emphasis on optimizing cycling performance with the use of cycle mounted power meters. Over the last decade, Dr. Lim has helped guide a number of teams and individual cyclists to collegiate, national, world, and Olympic medals. This last year, however, he has focused primarily on advising **Floyd Landis** bringing a unique blend of practical, scientific, and philosophical insight to Floyd's Tour de France preparation.

Bicycling

Powerfeed: Peak Power

Landis finds himself having a consistently paced day

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Stage 9: Sunday, July 10th

Route: Gerardmer to Mulhouse

Type: First mountain stage with 4 category 3 climbs, 1 category 2 climb, and 1 category 1 climb.

Distance: 171 km

Elevation Change: -421 meters or -1,382 feet loss (Average pt to pt grade = - 0.25%)

Total Feet Climbed: 2,552 meters or 8,373 feet

Average Elevation: 637 ± 271 meters of 2,091 ± 890 feet above sea level

Minimum Elevation: 245 meters or 804 feet

Maximum Elevation: 1338 meters or 4,390 feet

Weather: 65° to 70°F. Cool...perfect riding weather.

Climbs:

1. Col de Grosse Pierre (Cat 3): 3.1 km at 6.4% beginning at 6.4 km point.
2. Col des Feignes (Cat 3): 9 km at 2.9% at 22 km point.
3. Col de Bramont (Cat 3): 3.4 km at 6.5% at 33.5 km point.
4. Le Grand Ballon (Cat 2): 21.9 km at 3.6% at 64 km point (High point of stage).
5. Col de Bussang (Cat 3): 6.2 km at 4.5% at 98 km point.
6. Le Ballon d'Alsace (Cat 1): 9.1 km at 6.8% at 115 km point.

At a Glance:

Stage Placing: 74th

GC Placing: 12th

Time: 04:14:24 (6 min & 4 seconds down on winner Michael Rasmussen)

Average Speed: 40.3 km/hr or 25.0 mph

Average Power: 259 Watts

Total Work: 3,953 Kjoules

Stress to Strain Index: 1.16

Predicted Average Power at For Floyd Alone: 350 Watts

% Savings due to Drafting: 26%

Stage 8 Recap:

Floyd was chomping at the bit in yesterday's race but was conservative, remaining patient and quiet. He had a good view of all the strong T-mobile attacks and is excited about the real racing that is yet to come. His legs feel good and after tomorrow's rest day we'll hopefully get to see how good. Otherwise, other than the psychological lift gained by others on the last climb, he didn't see yesterday's stage as all that significant. He was quick to mention that doing an effort like they did yesterday is not that big of a deal if you only have to do it once. As we saw, there are probably 30 or so guys who can do that. But, only half those guys can do that twice, and only 1/3rd can do it three times. So when we get into hard consecutive climbs in the Alps and Pyrenees, it will be a completely different race.

Since I drew an analogy in the Stage 8 article between a power meter and the thermometer, I thought I'd quickly add that even though we can objectively measure temperature, everyone has a different perception of how hot or how cold it is on any given day. This is especially true if it's windy or humid. Likewise, depending on the type of course or environment, how steady or unsteady the pace is, and how fresh or tired a person is, their perception of how hard or easy a ride is might change. So to extend the analogy, in the same way, we often use a "wind chill factor" or "heat index" to correct for temperature, we use the "stress to strain index" to correct for how hard Floyd feels the stage was relative to his actual power. When you look at the total work done in the table, think of that as the actual temperature. Then when you look at the total work done from perceived exertion or RPE, think of that as the wind chill factor for the day.

Stage 9, Still Waiting for More:

Today Floyd came in with his highest average power output of the Tour. However, at just over 4 hours of riding, the total work of 3,953 Kjoules he did today is only slightly higher than the Tour average. In that sense, it was definitely more of a consistently paced day, but with not too much energy expended, the stage was not as difficult as it could've been or as hard as it looked on paper. In fact, though today's profile looked much more aggressive than yesterday's, the 8,373 feet of climbing today was only about 2,000 feet more than yesterday. Also, remember that in much of Floyd's pre-Tour training, he would consistently put in 5,000 to 6,000 Kjoule days with 10,000 to 15,000 feet of climbing. So we know he can handle the work.

The question at hand, however, is how repeated accelerations and surges within a race affect a rider's ability to handle a given amount of work. That is, riding steady by yourself, even at the same average power output or total work, is not quite the same as racing where a hard combination of attacks or surges can end your day before it even begins.

To keep an eye on this we pay careful attention to two things in the data table. First, we look at the peak power outputs he achieves, especially for the 5-minute and 30-minute time frames since most serious attacks occur in this time frame. Second, we look at how much time he spends at and above his lactate threshold, as time accumulated in these intensity zones is exponentially harder than time accumulated below. In today's data, you'll notice that Floyd achieved new highs values for his 30-second peak power, his 1-minute peak power, and his 5-minute peak power. Although this new high for 5-minute peak power is a bit of a flag that today there was a serious punch thrown, Floyd's peak power for 10-minutes and for 30-minutes was much lower than yesterday's. In addition, that 5-minute peak occurred on the first climb of the day, when riders are fresh and probably antsy to test their legs. It'd be a different story if that peak occurred late in the race when everyone is already fatigued.

Also, note that in today's stage, Floyd spent 1 hour and 53 minutes at or above his lactate threshold. Though this is only 5 more minutes than he spent at these intensities compared to yesterday, he did achieve new highs for the Tour for time spent at "lactate threshold" and at "race pace."

Based on all of the data, I'd say it's a toss up as to whether today was really any more difficult than yesterday. So since, the numbers are ambiguous, I'll turn to the man

himself who has just swallowed two pears whole. He's not responding, so I'll just use how I'm feeling relative to how Floyd is looking as a comparison. From my view here in the bus, it looks like Floyd's on a beach in Hawaii, while I'm getting pounded in rush hour traffic. He's showered, clean, smiling and about to get on a plane to Grenoble. I'm sweating, stressed, a bit disoriented and about to drive 5 hours to the same location. So I'd say today was just like the other. The man is good.

Some Thoughts on Peak Power:

Because, I'm often referring to Floyd's peak power data, I'd thought I'd take a little bit of time and officially introduce this very important variable. I'll start by saying that everyone is always asking me what Floyd's maximum power is. As if, he's some sort of racecar and they want a horsepower rating before they haggle with the salesman.

The reality is, there is no such thing as a single maximum power output value for a cyclist. Rather, there are different maximum or peak power values for different time frames. So instead of saying that Floyd's max power is an arbitrary 475 watts, I can say for 5 minutes the highest we've ever seen him hold is 475 watts. That's also why we use the term "peak" instead of "max." When we say "peak," it's a subtle distinction that means the value is the highest we've ever measured to date. When we say, "max," there's the understanding that the value is the highest that has ever and will ever be measured. Since Floyd is still improving, we stick with peak. When he retires, we'll tell you what his max was.

In any case, just like runners can have personal bests or PR's for different distances (the mile, a 10 km run, or a marathon), a cyclist can have personal bests or peaks for different time frames. We measure those bests as the highest wattage a cyclist can for a distinct time period. In our case, we measure the highest power Floyd holds each day for 5 seconds, 30 seconds, 1 minute, 5 minutes, 30 minutes, 1 hour, and 2 hours. The reason why we chose these different time frames is because performing all out for each requires a distinct combination of physiological attributes. As an example, going all out for 5 seconds is really dependent on anaerobic energy sources (i.e., energy production without the use of oxygen), whereas going all out for 2 hours is completely dependent on aerobic energy sources (i.e., energy production exclusively through the use of oxygen). In addition, an all out effort for 5 minutes is very close to an athlete's maximal aerobic capacity or VO2 max while an all out effort for 30 minutes to 1 hour is very close to an athlete's lactate threshold.

Since, these different time frames place distinct physiological demands on the body, cyclists who are better at sprinting tend to have better peak power outputs in the 5 second to 1 minute time frame, while cyclists who are better at time trialing or climbing normally have better peak power outputs for the 5 minute to 2 hour time frame. A sprinter here at the Tour might be able to hold 1700 or more watts for 5 seconds while Floyd probably won't crack 1000 watts. On the other hand, Floyd will probably be able to hold over 400 watts for 30 minutes, while a sprinter of equal weight will be lucky to hold over 350 watts.

Regardless of the type of cyclist, however, there is an exponential or cubic like relationship between a given time frame and the power that can be held. In other words, there's a real fast and steep drop in peak power output between 5 seconds and 1 minute, and a smaller drop between 5 minutes and 30 minutes, and a shallow drop between 1 hour and 2 or more hours.

Ultimately, we know what Floyd's all time peaks are for each time frame and here at the Tour we keep a daily check not only on how each day's values compares to the other but how each day's values compare with what we know his best to be. Although we expect him to record new PR's here at this year's Tour, I'll just say that we haven't seen them yet. But I'm sure we will.

For a reference table of peak power values for pro cyclists and your average Jane and Joe, take a look at **tables 2 and 3**.

Table 1. Floyd's power data for Stage 9. A higher average power today, but with less time, the total work was not much higher than the average for the Tour. Overall a more consistent day of work for Floyd with new high peak power outputs at 30 seconds, 1 minute, 5 minutes and 2 hours. For the first climbing day, not quite as hard as yesterday in terms of climbing, but more climbs and still more time at LT and race pace zones.

| | Stage 9 | Tour Average | Min | Max |
|------------------------------|-------------|----------------------|-------------|--------------|
| Basic Stats | | | | |
| Duration (hours:min) | 4:14 | 4:24 ± 0:32 | 3:46 (S5) | 5:04 (S8) |
| Distance (miles) | 106 | 125 ± 15 | 113 (S5) | 144 (S8) |
| Average Speed (mph) | 25.0 | 28.4 ± 1.65 | 25.0 (S9) | 30.1 (S5) |
| Perception of Effort (1-10) | 6 | 4.9 ± 0.8 | 4 (S2, S3) | 6 (S8, S9) |
| Average Cadence (RPM) | 83 | 86.3 ± 3 | 81 (S6) | 90 (S2) |
| Average Power (Watts) | 259 | 232 ± 19 | 208 (S2) | 259 (S9) |
| Work from Power (KJoules) | 3953 | 3687 ± 631 | 2855 (S2) | 4639 (S8) |
| Work from RPK (KJoules) | 4579 | 3915 ± 900 | 2772 (S2) | 5470 (S8) |
| Stress to Strain Index | 1.16 | 1.06 ± 0.11 | 0.88 (S3) | 1.38 (S8) |
| Peak Power | | | | |
| 5 sec (Watts) | 755 | 847 ± 83 | 760 (S6) | 965 (S8) |
| 30 sec (Watts) | 645 | 558 ± 66 | 465 (S2) | 645 (S9) |
| 1 min (Watts) | 555 | 466 ± 55 | 403 (S2) | 555 (S9) |
| 5 min (Watts) | 478 | 382 ± 63 | 308 (S2) | 478 (S9) |
| 30 min (Watts) | 337 | 297 ± 51 | 249 (S2) | 296 (S9) |
| 1 hour (Watts) | 360 | 270 ± 36 | 231 (S2) | 333 (S8) |
| 2 hours (Watts) | 287 | 244 ± 21 | 227 (S2) | 287 (S9) |
| Zone Distribution | | | | |
| Zero Watts (% or min) | 12.5% or 32 | 12.4 ± 2% or 32 ± 5 | 26 min (S8) | 41 min (S7) |
| Recovery (% or min) | 17.2% or 44 | 25 ± 5% or 69 ± 14 | 44 min (S9) | 89 min (S7) |
| Endurance (% or min) | 31.2% or 81 | 53 ± 2% or 88 ± 13 | 72 min (S2) | 102 min (S8) |
| Lactate Threshold (% or min) | 14.0% or 36 | 9 ± 2% or 25 ± 7 | 17 min (S2) | 36 min (S9) |
| Race Pace (% or min) | 12.3% or 31 | 8 ± 2% or 20 ± 7 | 12 min (S2) | 31 min (S9) |

Powerfeed: How Hard Is That Climb?

Is the Tour's system or rating climbs flawed?

By Allen Lim PhD

Stage 10: Tuesday, July 12th

Route: Grenoble to Courchevel

Type: Mountain top finish with two category 1 climbs.

Distance: 192.5 km

Elevation Change: 1780 meters or 5840 feet gain (Average pt to pt grade = 0.92%)

Total Feet Climbed: 3,293 meters or 10,804 feet

Average Elevation: 801 ? 577 meters of 2,627 ? 1893 feet above sea level

Minimum Elevation: 220 meters or 722 feet

Maximum Elevation: 2000 meters or 6,562 feet

Weather: 60° to 75°F and clear. Another perfect day for riding.

Climbs:

1. Cornet de Roselend (Cat 1): 20.1 km at 6.0% ending at 118 km point.
2. Courchevel (Cat 1): 22.2 km at 6.2% ending at 192.5 km point.

At a Glance:

Stage Placing: 11th (4 min & 16 seconds down on Lance Armstrong)

GC Placing: 10th

Time: 04:52:49 (2 min & 14 seconds down on winner Alejandro Valverde)

Average Speed: 36.5 km/hr or 23.0 mph

Average Power: 268 Watts (Floyd Predicted)

Total Work Estimate: 4,700 Kjoules (Floyd Predicted)

Stress to Strain Index: 1.48

No Excuses from Floyd:

There were a lot of expectations for today's first major mountain stage. In the end, Floyd gave it everything he had, but was not there in the final. Still, he is still amongst many of the favorites and it is still a very long and difficult race to come. As the days get more and more difficult it will be important for him to ride within himself and let his natural ability to recover and his natural endurance bring him up the standings. **My Opinion:**

In some ways, I feel that the ride today wasn't hard enough to suit his strengths. Since it was the first major mountain stage immediately after a rest day, there were definitely more guys who were fresh. That combined with only two major climbs and a rejuvenated Discovery team made it a hard day for everyone. As the days wear on and fatigue mounts across the peloton, I really do believe Floyd will begin to shine. It's been a tough race so far, but adversity is a good thing and I'm looking forward to seeing Floyd shine in the really arduous days to come. I know it's what he really thrives on.

It Won't Happen Again:

I am sorry to report that we don't have any power data to report today. Floyd got a rear flat very early in the stage and in the confusion was not able to get a Power Tap rear, despite there being spares in the car. The mechanics tell me it won't happen again as they know the power data is extremely important to Floyd. In particular, it's really the days that don't go as planned that are the most important to us. It's finding the weaknesses that give you the real foundation for becoming stronger.

©Allen Lim

How the Power Tap Helps Floyd in the Here and Now:

An article or two back, I mentioned that one of the primary reasons why we are collecting all the power data here is to have a basis for future training strategies. That's one of the reasons why not getting today's data is really disappointing.

I was recently asked, however, how the data helps Floyd real time on the bicycle. The major way it helps him is that it gives him instantaneous feedback to help him gauge his efforts and to help remind him to stay within the parameters of a particular strategy we may have set.

Although, Floyd is extremely in tune with his body, that highly developed sense of feel has been developed almost entirely by constantly seeing his power values flashed before him while racing and training. In fact, in the last year, today was the first day, outside of a time trial, that Floyd did not have the power meter. The thing missed most from having it on the bike today, were the constant reminders of where he's at, that in a millisecond help him to calibrate his effort. In the end, it helps to keep him relaxed and focused on his own ride in the middle of all the chaos of racing. The information can help him temper his efforts on attacks or help him establish a more optimal pace for himself on a climb. On the flats, watching the meter was one of the main

ways he is able to conserve so much energy. It nags him to find the sweet spots in the pack and float. In fact, he found that just a little farther back from the nose of the pack he was able to save significantly more energy without compromising his safety. That may explain why many of our predictions for energy saving from drafting hovered around 50% for the flat stages, compared to the 40% that is commonly reported.

Still, in the middle of a race, it's often about just going for it. The numbers aren't there to obsess about or there to dictate the race. They are there for feedback and to help record information in a way that is more objective than our best memory of the race.

How Hard is That Climb?

Because I didn't have any power data to analyze, I took the time to crunch way too many numbers in an attempt to figure out a question that has been bothering me for a really long time now. That question has to do with the Tour de France organization's system for rating all the climbs during the race and what those different categories really mean.

The climbs in the Tour are rated using a 4-category system. In reality, there are 5 categories of climbs. The categories are based on 3 major factors. They are 1) the steepness of the climb, 2) the length of the climb, and 3) the position of that climb along the course. Theoretically, a really steep and long climb occurring late in the race would receive the most difficult rating. A climb can be rated a 1, 2, 3, 4 or Hors Catégorie (HC). The easiest climb is a category 4 rated climb, while a 3, 2, and 1 are incrementally harder. The "Hors Catégorie" is a climb that is so difficult that it is beyond categorization. In my mind they should just add another number to the scale and they should reverse the order so a 1 is easiest, etc. In any case, the climb categorization is then used to determine the value of points given for the best climber or "Polka Dot" jersey competition with more points are given on the harder climbs.

To find out exactly how hard each climb in the Tour is, I actually entered every single category 1 to 4 and out of category climb into a spread sheet and looked at the following factors:

A. The point on the course where a climb as a percentage of the total distance that day.

B. The percent grade of the course.

C. The total distance of the climb.

D. The total feet climbed.

E. The elevation of the climb.

Based on these factors, I figured that if the category system established by the Tour did actually mean something, then by multiplying or adding the percent grade, the % at which the climb occurred, and the length of the climb, I could get a "Difficulty Index" that would actually tell me how hard a given climb is.

What I found, though, was that my system, which actually did take into account the steepness of the climb, the length of the climb, and the position of that climb along the course, was only related to the Tour's 1-4 to HC system 65% of the time. After all that work, that finding made me really angry. So I then decided to be an even bigger nerd and figure out what factors were best related to the Tour's ranking system. I found that if I just took into account the climbs length and steepness, I could predict the actual Tour category 80% of the time. So long story short, the Tour's category system from what I can tell is best related to the length and steepness of the climb and only predicts the length and steepness 80% of the time. In my mind the system is flawed. I shared this information with some of the riders and they laughed at me saying that they could've just told me that the rating system was completely arbitrary. I guess if you are going all out for 3 weeks whether your going up or down has no bearing on how hard you think things are.

Anyway, here are some interesting things I learned about the climbs in of the Tour.

For all 64 categorized climbs:

% Grade:

Average: $5.5 \pm 1.6\%$

Minimum: 2.9%

Maximum: 10.1%

Length of Climb:

Average: 6.8 ± 6.0 Km

Minimum: 0.9 Km

Maximum: 25.4 Km

Elevation Gain:

Average: $1,271 \pm 1,230$ feet

Minimum: 105 feet

Maximum: 5,059 feet

For all 22 Category 4 Climbs:

% Grade:

Average: $4.6 \pm 1.1\%$

Minimum: 2.9%

Maximum: 6.6%

Length of Climb:

Average: 2.7 ± 1.9 km

Minimum: 0.9 km

Maximum: 8.3 km

Elevation Gain:

Average: 363 ± 187 feet

Minimum: 105 feet

Maximum: 791 feet

For all 19 Category 3 Climbs:

% Grade:

Average: $5.3 \pm 1.2\%$

Minimum: 2.9%

Maximum: 7.1%

Length of Climb:

Average: 4.3 ± 2.6 km

Minimum: 1.2 km

Maximum: 11.3 km

Elevation Gain:

Average: 675 ± 262 feet

Minimum: 190 feet

Maximum: 1,168 feet

For all 8 Category 2 Climbs:

% Grade:

Average: 5.6 ± 2.1%

Minimum: 3.6%

Maximum: 10.1%

Length of Climb:

Average: 11.7 ± 5.9 Km

Minimum: 3.1 Km

Maximum: 21.9 Km

Elevation Gain:

Average: 1,829 ± 533 feet

Minimum: 1,017 feet

Maximum: 2,585 feet

For all 10 Category 1 Climbs:**% Grade:**

Average: 7.2 ± 0.8%

Minimum: 6.0%

Maximum: 8.3%

Length of Climb:

Average: 11.6 ± 5.4 Km

Minimum: 7.0 Km

Maximum: 22.2 Km

Elevation Gain:

Average: 2,620 ± 919 feet

Minimum: 1,850 feet

Maximum: 4,492 feet

For all 5 Hors Category Climbs:**% Grade:**

Average: 7.3 ± 0.9%

Minimum: 6.1%

Maximum: 8.3%

Length of Climb:

Average: 17 ± 5.5 Km

Minimum: 10.3 Km

Maximum: 25.4 Km

Elevation Gain:

Average: 3,939 ± 805 feet

Minimum: 2,789 feet

Maximum: 5,059 feet

Hardest climb based on steepness, length, and location on course:

- Today's last climb Courchevel at 6.2% grade for 22.2 Km (2,070 feet to 6,563 feet for a gain of 4,492 feet)

Hardest climb based on just steepness and length:

- Tomorrow's climb up the Col de Madeleine at 6.1% grade for 25.4 Km (1,503 feet to 6,562 feet for a gain of 5,059 feet)

*Dr. Allen Lim is an exercise physiologist and coach with **Thrive Health Fitness Medicine**. He received his doctorate at the University of Colorado at Boulder where his research focused on health and human performance with a specific emphasis on optimizing cycling performance with the use of cycle mounted power meters. Over the last decade, Dr. Lim has helped guide a number of teams and individual cyclists to collegiate, national, world, and Olympic medals. This last year, however, he has focused primarily on advising **Floyd Landis** bringing a unique blend of practical, scientific, and philosophical insight to Floyd's Tour de France preparation.*

Bicycling

Powerfeed: Consistency Over The Long Haul

Tactics and terrain of stage produce new max values

By Allen Lim PhD

Stage 11: Wednesday, July 13th

Route: Courchevel to Briancon

Type: Mountain stage with two HC category climbs and a category 1 climb.

Distance: 173 km

Elevation Change: -237 meters or -449 feet loss (Average pt to pt grade = - 0.08%)

Total Feet Climbed: 3,846 meters or 12,619 feet (Most climbing to date)

Average Elevation: 1277 \pm 580 meters of 4,191 \pm 1,904 feet above sea level

Minimum Elevation: 458 meters or 1,503 feet

Maximum Elevation: 3,645 meters or 8,678 feet

Weather: 70 to 75°F. Mostly clear skies all day.

Climbs:

1. Col de Madeleine (HC): 25.4 km at 6.1% beginning at 25.4 km point.
2. Col du Telegraphe (Cat1): 12 km at 6.6% at 98 km point.
3. Col de Galibier (HC): 17.5 km at 6.9% at 115.5 km point.

At a Glance:

Stage Placing: 19th

GC Placing: 11th

Time: 04:48:53 (1 min & 15 seconds down on winner Vinokourov)

Average Speed: 35.9 km/hr or 22.3 mph

Average Power: 285 Watts

Total Work: 4,940 Kjoules

Stress to Strain Index: 1.23

Feeling Better:

Today was great for the team with Floyd getting a pretty comfortable ride into Briancon, following wheels as his teammates Santiago Botero and Oscar Pereiro went on the attack on some of the longest and consistently steep climbs of the Tour. In the end Botero was able to stay away with Alexandre Vinokourov but got out sprinted at the line. It was still an exceptional day for Botero who won here in Briancon 5 years ago. He's beginning to show serious form and the team as a whole is feeling good about their options in the stages to come.

Floyd in particular felt a lot better compared to **yesterday's mountain top finish in Courchevel**. He was super excited for his teammates as he rolled into the bus today, raising his arms in victory as if they had won the race. Regardless of the outcome it is always a great feeling to finish a race knowing that the team was able to execute without mishap or mistake.

Today's Power:

The power data from today really reflects the tactical and terrain features of the day. In particular, the race produced a couple of significant new max values. A new high average power of 285 Watts, a new high workload of 4,940 Kjoules, a new high perceived workload of 6,067 Kjoules, a new max power output for 1 hour (359 Watts) and 2 hours (315 Watts), and an almost two fold increase in the time spent at lactate threshold (66 minutes) and race pace (44 minutes).

Table 1

These new highs reflect a more even pace across the day. With Botero and Pereiro on the attack and Discovery setting a constant tempo to keep them in check, the intensity was elevated all day but lacked the same kind of high intensity or supra-maximal surges that we've seen in previous stages. In addition, with some of the longest and consistently graded climbs that we will see in this Tour, the terrain called for consistency over the long haul rather than short attacks.

Though it could be said that **this stage** was the hardest yet, it was hard in a different way. The overall power and work came up, but with average values for time spent in Floyd's max and supra-max zones as well as unremarkable peak power outputs for 1, 5, and 30-minutes it is unlikely that there were too many in the red today - a scenario that is reflected by the larger lead finishing group. The power from today also demonstrates that even though something may look really tough on paper it's how an individual, or the peleton as a whole, chooses to ride it that makes the day easy or difficult. In fact, today Floyd came nowhere close to the peak power outputs for 5, 10, and 30-minutes that he achieved in stage 8 and 9 on climbs that were rated significantly lower than the ones today.

Calculating Power Old School: A Look at "VAM"

Because the grade and pace on today's climbs were so consistent, it is possible to do a quick check of the power numbers using calculations that for some are still

| | Stage II | Tour Average | Min | Max |
|------------------------------|-------------|-----------------------|--------------|--------------|
| Basic Stats | | | | |
| Duration (hrs:min) | 4:48 | 4:30 ± 1:30 | 3:46 (S5) | 5:04 (S8) |
| Distance (miles) | 107 | 121 ± 14 | 107 (S11) | 144 (S8) |
| Average Speed (mph) | 22.5 | 27.1 ± 2.92 | 22.3 (S11) | 25.0 (S9) |
| Perception of Effort (1-10) | 7 | 5.5 ± 1.4 | 4 (S2, S3) | 8 (S10) |
| Average Cadence (RPM) | 81 | 85.0 ± 3.5 | 81 (S6, S11) | 90 (S2) |
| Average Power (Watts) | 285 | 242 ± 26 | 206 (S2) | 285 (S11) |
| Work from Power (KJoules) | 4940 | 3944 ± 748 | 2855 (S2) | 4940 (S11) |
| Work from RPE (KJoules) | 6067 | 4500 ± 1420 | 2772 (S2) | 6067 (S11) |
| Stress to Strain Index | 1.21 | 1.12 ± 0.17 | 0.88 (S5) | 1.48 (S10) |
| Peak Power | | | | |
| 5 sec (Watts) | 757 | 816 ± 84 | 757 (S11) | 963 (S8) |
| 30 sec (Watts) | 553 | 558 ± 56 | 465 (S2) | 645 (S9) |
| 1 min (Watts) | 505 | 471 ± 51 | 403 (S2) | 555 (S9) |
| 5 min (Watts) | 431 | 388 ± 60 | 308 (S2) | 478 (S9) |
| 30 min (Watts) | 363 | 305 ± 53 | 249 (S2) | 386 (S8) |
| 1 hour (Watts) | 359 | 281 ± 46 | 231 (S2) | 359 (S11) |
| 2 hours (Watts) | 315 | 250 ± 32 | 227 (S2) | 315 (S11) |

©Allen Lim

the norm for estimating a rider's fitness and power.

That technique is often referred to as calculating a rider's "VAM" or Vertical Ascent rate in Meters per hour. It's based on the simple premise that the faster you climb up a hill the more power you have to be producing. Indeed, the physics of riding up a steep climb (? 7% grade) is actually quite simple. Thus, measuring how fast someone moves up a hill is one of the simplest ways to derive power.

Up a steep hill, about 90% of the power a cyclist produces is used to overcome gravitational resistance, which is a function of body and bicycle weight. At the same speed, a heavier cyclist will produce a higher power output than a lighter cyclist on a given climb. That's why when we talk about climbing ability we almost always talk about it in terms of a cyclist's power to weight ratio rather than the absolute power.

For example, to stay with the lead group today on the Galibier, you would've had to produce about 5 to 5.5 Watts per Kilogram of body weight. For an average Tour cyclist who weighs 70 Kg or 154 pounds, that would be 350 to 375 Watts. For a lighter cyclist weighing 60 Kg their power would only have to be 300 to 330 Watts.

In either case, if we know a cyclist's body and bicycle weight, the elevation gain over the course of a hill, and their time up a hill, we can get a decent estimate of their power output. The calculation is as follows:

$$\text{Power (W)} = (\text{Total Mass in Kg} \times 9.8 \times \text{Elevation Gain in Meters}) \div \text{Time in Seconds}$$

As an example, up the Galibier today the riders gained 3,954 feet in elevation or 1,205 meters. Let's say it takes them 45 minutes to get to the top (2,700 seconds) and that the average rider is 70 Kg (154 lbs) with a bike weight of 6.8 Kg (15 lbs). Thus, their power for that time would be equal to:

$$\text{Power} = (76.8 \text{ Kg} \times 9.8 \times 1,205 \text{ Meters}) \div 2,700 \text{ seconds} = 336 \text{ Watts}$$

Remember, however that the power to get up the hill is only about 90% of the total power. The additional 10% is used to overcome a small amount of aerodynamic and rolling resistance. Thus if we add 10% to this value we get a total of 370 Watts to climb the Galibier in 45-minutes.

Since a cyclist's power is just proportional to their rate of ascent, you don't really have to calculate the actual power output to appreciate how powerful a cyclist is. Instead old coaches and directors would just calculate the rate of ascent in meters per hour using altitude watches while following a rider or the pack. So another way to look at climbing effort is to simply say that if you can climb the Galibier in 45 minutes, you would be climbing 1,205 meters in 45 minutes or a VAM of 1607 meters per hour.

Most professional cyclists can achieve a VAM of 1400 to 1500 meters per hour. Really great climbers can climb at a VAM of 1600 to 1700 meters per hour. Finally, there are a select few (Pantani, Mayo, Armstrong) who have broken the holy grail or 4-minute mile of climbing speed - a VAM of 1800 meters per hour which is equal to about 6.3 Watts per Kilogram of body weight up an 8% grade. That's 455 Watts for Lance Armstrong up L'Alp D'Huez last year. Remember, however that the power to get up the hill is only about 90% of the total power. The additional 10% is used to overcome a small amount of aerodynamic and rolling resistance. Thus if we add 10% to this value we get a total of 370 Watts to climb the Galibier in 45-minutes.

Since a cyclist's power is just proportional to their rate of ascent, you don't really have to calculate the actual power output to appreciate how powerful a cyclist is. Instead old coaches and directors would just calculate the rate of ascent in meters per hour using altitude watches while following a rider or the pack. So another way to look at climbing effort is to simply say that if you can climb the Galibier in 45 minutes, you would be climbing 1,205 meters in 45 minutes or a VAM of 1607 meters per hour.

Most professional cyclists can achieve a VAM of 1400 to 1500 meters per hour. Really great climbers can climb at a VAM of 1600 to 1700 meters per hour. Finally, there are a select few (Pantani, Mayo, Armstrong) who have broken the holy grail or 4-minute mile of climbing speed - a VAM of 1800 meters per hour which is equal to about 6.3 Watts per Kilogram of body weight up an 8% grade. That's 455 Watts for Lance Armstrong up L'Alp D'Huez last year. In any case, it's really nice to see that what Floyd actually did is extremely close to what we predict for the terrain and speed. Specifically, on today's final climb, the lead group averaged 20.5 km/hr or 12.7 mph and climbed at a rate of 1413 meters per hour, which is well within the capacity of many riders here in the Tour. This VAM combined with the actual power readings at our disposal is further confirmation for the final group size.

Ultimately, if there's a lesson in all the calculations I just listed out here, it's that you can't just blindly trust the numbers you get from a power meter, nor can you assume that riding conditions are consistent enough that you can always know how hard a cyclist is going just by looking at their speed or VAM. In the end, you need both. A little bit of old school to confirm the new school and a little bit of new school to give props to the old.

For a detailed look at how the percent grade and speed affect absolute power output, power output normalized to weight, VAM, and the % of power used to overcome gravity see **Tables 2, 3, 4, and 5**.

Table 2. Power required for different speeds and grades in a 154 lb rider.

| | | Power Required for a Given Speed (mph) and Grade (%) for a 70 kg (154 lb) Person with a 6.8 kg (15 lb) Bicycle | | | | | | | | | |
|-------------|-----|---|-----|-----|-----|-----|-----|-----|------|------|------|
| Speed (mph) | S | Percent Grade | | | | | | | | | |
| | | 1% | 2% | 3% | 4% | 5% | 6% | 7% | 8% | 9% | 10% |
| 7.5 | 27 | 11 | 61 | 78 | 95 | 112 | 129 | 145 | 162 | 179 | 197 |
| 10 | 45 | 50 | 95 | 120 | 146 | 171 | 196 | 221 | 247 | 272 | 297 |
| 12.5 | 67 | 100 | 134 | 168 | 202 | 235 | 269 | 303 | 337 | 370 | 404 |
| 15 | 94 | 136 | 178 | 220 | 262 | 304 | 346 | 388 | 430 | 472 | 514 |
| 17.5 | 130 | 180 | 231 | 281 | 332 | 382 | 433 | 483 | 534 | 584 | 634 |
| 20 | 174 | 232 | 292 | 351 | 410 | 469 | 529 | 588 | 647 | 706 | 765 |

Table 3. Power to weights (Watts per Kg of body weight) required for different speeds and grades. Data is based on a 154 lb rider with a 15 lb bicycle. Generally speaking, the cyclist with the highest power to weight ratio can maintain the highest climbing speed. Many pro cyclists can hold between 5 to 5.5 watts per kg for sustained periods (10 to 60 minutes) while climbing.

| | | Power to Weight (Watts per Kg) for a Given Speed (mph) and Grade (%) for a 70 kg (154 lb) Person with a 6.8 kg (15 lb) Bicycle | | | | | | | | | |
|-------------|------|---|------|------|-------|-------|-------|-------|-------|-------|-------|
| Speed (mph) | S | Percent Grade | | | | | | | | | |
| | | 1% | 2% | 3% | 4% | 5% | 6% | 7% | 8% | 9% | 10% |
| 7.5 | 0.39 | 0.63 | 0.87 | 1.11 | 1.35 | 1.60 | 1.84 | 2.08 | 2.32 | 2.56 | 2.80 |
| 10 | 0.64 | 1.00 | 1.36 | 1.72 | 2.08 | 2.44 | 2.80 | 3.16 | 3.52 | 3.88 | 4.24 |
| 12.5 | 0.95 | 1.43 | 1.92 | 2.40 | 2.88 | 3.36 | 3.85 | 4.33 | 4.81 | 5.29 | 5.77 |

Table 4. The calculated VAM or vertical ascent rate in meters per hour at different speeds and % grades. Notice that you're the steeper the

climb the higher the VAM at any given speed. Because, the percentage of power due to gravitational resistance increases at steeper grades, VAM should only be used to calculate power at % grades of 6% or greater. Ideally, an 8 to 10% grade should be the only hills used to estimate power from VAM.

Ascent Rate (Meters per Hour) for a Given Speed (mph) and Grade (%)
for a 70 kg (154 lb) Person with a 6.8 kg (15 lb) Bicycle

| Speed (mph) | Percent Grade | | | | | | | | | |

Powerfeed: Coasting Through

Stage 12: Becoming A Better Climber

By Allen Lim PhD

Thursday July 14th

Route: Briancon to Digne-les-Bains
Type: Mountain Stage
Distance: 187 km or 116 miles
Elevation Change: -588 meters or -1,929 feet loss (Average pt to pt grade = - 0.31%)
Total Feet Climbed: 1,740 meters or 5,709 feet
Average Elevation: 973 \pm 225 meters of 3,194 \pm 737 feet above sea level
Minimum Elevation: 636 meters or 2,087 feet
Maximum Elevation: 1,346 meters or 4,416 feet
Weather 80° to 86°F. Summer is here. It's getting hot.

Climbs:

Cote des Demoiselles-Coiffees (Cat 3): 4.6 km at 4.8% beginning at 54 km point.
 2. Col Saint Jean (Cat 2): 13.2 km at 4% at 75 km point.
 3. Col du Labouret (Cat 4): 2.2 km at 3.2% at 113 km point.
 4. Col du Corobin (Cat 2): 12.4 km at 4.5% at 142 km point.
 5. Col de l'Ome (Cat 4): 2.7 km at 3.9% at 175 km point.

At a Glance:

Stage Placing: 84th
GC Placing: 11th
Time: 04:30:39 (10 min & 33 seconds down on winner David Moncoutie)
Average Speed: 41.5 km/hr or 25.7 mph
Average Power: 231Watts
Total Work: 3,751 Kjoules
Stress to Strain Index: 1.08

Predicted Average Power at For Floyd Alone: 310 Watts

% Savings due to Drafting: 25.5%

Some Thoughts on Previous Thoughts:

On the drive to the finish today, I started thinking a lot more about a question I alluded to in **yesterday's report**. It was the question about how much rider's actually save when they're "drafting" or perhaps better stated, "following wheels" on the climbs. The bottom line is, I think I'm right about the very small 7-watt drafting related saving while climbing on the Galibier yesterday. Though those 7 watts only represented 2% of the total 342 watts required for Floyd to get up the Galibier, the aerodynamic resistance holding him back was only 37 watts or about 11% of the total power. On the other hand, that 7-watt saving represents 19% of the total aerodynamic drag cost. Since aerodynamic resistance increases with the velocity squared, there would be proportionally less savings from drafting at slow speeds. On yesterday's climb the average speed was only 12.7 mph. So the numbers check out. For the most part, trying to draft on yesterday's climb was more of a psychological boost and also a way to help keep one's pace steady. In the end, if the climbing speed is less than 15 mph, there is minimal benefit to drafting. But if it's higher than 15 mph, you better find a wheel and hold on.

I also started thinking a lot about how hard each of these mountain stages are with respect to the climbing load. In particular, it was a comment that Floyd made last night that this stage was going to be one of the easiest climbing days. So I took the ranking I developed based on the distance and steepness of each climb and ranked every single stage with climbing points according to their difficulty. That ranking is presented in table 2. In summary, today's stage only ranked 8th out of 18, with respect to climbing difficulty. More importantly, the hardest and 3rd hardest day of climbing are still to come.

Thoughts on Today's Power:

The most exciting thing to report about today's data is that Floyd hit a new all Tour high for coasting at zero watts of 42 minutes beating stage 7's high by 1 minute. That's right, today Floyd coasted for 42 minutes. Otherwise, today was so average it was kind of weird. In addition, it really looked more like one of the early flat stages than a mountain stage. Check out the numbers in Table 1. If I were just looking at the power data, I wouldn't be able to tell that this was suppose to be a mountain stage. Indeed, of the mountain stage days, the total amount of climbing was the lowest at 5,709 feet. So for today, climbing ability didn't have much to do with the final results.

Floyd's Climbing Program:

Of course, a rider's ability to climb is one of the most if not the most important assets he has at the Tour. For Floyd it was what he focused on the most this year. Consequently, I thought it'd be neat to share exactly what he did this last year to prepare for the hills and outline a little hill climbing training program that others can scale down for their own preparation.

In short, our conversation about training for the mountains early this year went something like this:

Me: So how much do you try to climb each month?

Floyd: About 150,000 vertical feet a month.

Me: You think you can do more?

Floyd: Yeah.

Me: Okay, cool. Then, I think you should do more.

Floyd: Sounds good.

And that was basically it. By the time Floyd got to the Tour, he had averaged 200,000 feet of climbing each month for the three months prior. That's an average of about 8,000 feet of climbing every time he went out to train and more than he had ever accomplished. This might sound like a lot, but if you look at the 9 major mountain stages in this year's Tour and total the elevation gain for each of the categorized climbs, the average is $8,784 \pm 2,710$ feet of climbing with a minimum of 4,882 feet (**today's stage**) and a maximum of 12,953 feet (**stage 15**). That's not counting all the little rollers and uncategorized hills the riders do.

While, it may sound over simplistic, the fact of the matter is, if you want to improve your climbing, you need to climb. The biggest mistake I see riders make in their hill climb training is they don't climb enough. No matter what you do, if you don't spend the time in the mountains you won't improve your climbing.

Just climbing more, however, wasn't the only thing involved in preparing Floyd for the hills. It only served as a baseline for more specific work. Just like it is sometimes important to establish a nice base of volume in the early season before any high intensity, it's sometimes good to just establish a big base of climbing volume. After that volume base is done, it's critical to start forcing yourself to handle a higher sustainable intensity. As you begin to raise that sustainable intensity the next step is attempting to vary the intensity on the climbs. Finally, no matter what you do, you won't climb at your best if you're not at an optimal weight. So if you're a bit or a lot overweight, all things being equal, you'll climb faster if your carrying less weight.

Below is a short review of the steps we took to make Floyd better on the hills as applied to you:

1. Volume

Before you start consulting any rocket scientists about how to improve your hill climbing, first, try climbing more and see what happens. When you do that climbing, don't worry about intensity or how hard you go. Just go as easy as you can to make it to the top and just try getting over the top of as many climbs as possible. If you live in an area that's not too hilly, doing repeats on a single hill is a viable solution. If you live in a place with no hills at all, then you'll just have to work on your overall fitness and not worry about it.

2. Hard and Steady

After you get comfortable just being in the hills a lot more, start focusing on going hard on those hills. Most importantly, on any length of climb, try keeping as high and sustainable pace on that hill as possible. If it's a short hill, then you'll be going harder than a longer hill. In the end, it's important to teach your body to go as hard as possible for any length of climb. Don't worry about blowing up either. Just think of it as positive feedback.

3. Negative Splits

Once you learn how to climb hard and steady, it's time to learn how to bring that intensity up a notch over the top of the climbs. That is, start doing hill intervals where you go a nice moderate tempo on the first half of the climb and then go crazy over the top. It's a great way to teach your body how to redline on the climbs and if you can handle it, it's always better to drop your competitors over the top of a climb so that you can recover from the effort on the descent.

4. Quarter Splits

One of the hardest things to do on a climb is accelerating and decelerating. While many can climb a solid steady pace, forcing someone to surge or being able to deal with someone else's surge can make or break your race. As an example, if you know you can hold 200 Watts on a hill, try breaking that same hill into 4 equal sections. On the first section, ride at 150 Watts, on the second, ride at 250 Watts, on the fourth 150 Watts, and on the last section bring it back up to 250 Watts. Although the average power will be exactly the same, you'll notice that the effort feels considerably harder. Thus, after learning how to negative split (1st half faster than the second half) a hill, it's important to start "quartering" your climbs.

5. Terrain based intervals

In racing, the surges and pace setting is rarely based on some fixed time or distance. Those surges or attacks happen relative to changes in the terrain. Accordingly, after a certain point in training, I usually throw away the clock with respect to intervals on the climbs and have riders simply use terrain features, as their cue for how long and hard different efforts should be. In racing, it's not like riders are going to go all out for a predefined 5 or 10 minutes and then sit up. They'll go hard all the way over the top, or attack on the steepest sections. Accordingly, Floyd will simply imagine how the attacks might play out on a given climb and try to mimic that in training.

6. Pre Climb Throttling

One important aspect of climbing in the Tour is being able to handle the hard place leading into the climb. It's a common tactic for the strong teams to have their non-climbing specialists to give the climbers a "lead out" into the hill. That is, they lift the pace really high coming into the hill to wear people out even more. For Floyd, this meant that by the time we got close to the Tour, I would motor pace him for 5 to 20 minutes before every major climb he did in training.

7. Losing Weight

Though, I'd rather just focus and recommend that people primarily focus on making their engine stronger, you can't ignore the fact that climbing speed is almost entirely dependent on a rider's power to weight ratio. Get down to an optimal weight and you'll go faster uphill. But get too skinny and you may lose valuable muscle mass and power. One final note, if you do decide to try and lose weight, do not try to lose more than a pound a week. In addition, if your friends or family start freaking out about how skinny you are, I would recommend listening to them. In my experience, athletes or anyone driven to succeed, are a poor judges of their own body image and that's all I'll say about that. Happy climbing.

Table 1. Floyd's power data for Stage 12.

Table 2. Stages with mountain points ranked in order of difficulty. The difficulty index is based on the steepness and grade of the climb.

Powerfeed: Battling Heat And Humidity

Stage 13: Today's weather conditions create challenges

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Friday, July 15th

Route: Miramas to Montpellier

Type: Flat Stage

Distance: 173.5 km or 107.6 miles

Elevation Change: -10 meters or -55 feet loss (Average pt to pt grade = - 0.01%)

Total Feet Climbed: 351 meters or 1,152 feet

Average Elevation: 79.1 ± 49 meters of 260 ± 160 feet above sea level

Minimum Elevation: 10 meters or 33 feet

Maximum Elevation: 185 meters or 607 feet

Weather: 80°F and 78% Humidity. Right on the high risk exercise edge.

Climbs:

1. Col de La Vavede (Cat 4): 1.1 km at 6.1% beginning at 25.4 km point.

At a Glance:

Stage Placing: 78th

GC Placing: 11th

Time: 03:43:14 (Same time as winner Robbie McEwan)

Average Speed: 46.6 km/hr or 28.9 mph

Average Power: 213Watts

Total Work: 2,853 Kjoules

Stress to Strain Index: 1.41

Predicted Average Power at For Floyd Alone: 424 Watts

% Savings due to Drafting: 50.2%

Not That Easy:

Today's power data is really interesting as Floyd hit a new low for time (3:43:14) and for work (2,853 Kjoules), but had a very high stress to strain index. There are a number of reasons why he thought the stage felt a lot harder than it actually looks from the power data. Those reasons include fatigue, a huge number of very short (5 to 10 second) accelerations, and most notably today's killer combination of clear skies, heat, and humidity.

After the first 3 minutes, the speed came up and stayed up for the entire race. With close to two weeks of racing (the last 3 in the Alps) it was amazing for me to see how high the speed was. At 28.9 mph today's speed was exactly the same speed as the average of the first 6 flat stages. But for most of the riders, it felt a lot harder and a lot faster.

Unlike those first flat stages the clouds and rain that followed the riders for the first week made way for an oppressively bright sun and a heat and humidity combination that is considered to be "high risk" conditions for exercise (Table 2).

The Bottle & Weight Count:

Besides racing today, all of the riders pounded through a whole lot of water bottles filled with the team's typical ice-cold carbohydrate and electrolyte solution. Today Floyd thinks that he drank about 12 bottles while on the bike. He thinks, because when you're going that fast in conditions like today, you're not really counting, just doing.

With each bottle holding 500 ml's of fluid, that's 6 liters or just over 1.5 gallons of fluid consumed while on the bike today. Still, when he got off the bike at the end of the stage he was 3 kilograms lighter than he was after breakfast this morning. That means he lost 3 liters (1 kilogram of water = 1 liter of water) of fluid by the end of today's race or close to 4.5% of his body weight despite all those bottles he went through on the bike. If we add it all up, then Floyd's total sweat loss was equal to 9 liters or 2.4 liters per hour.

The last two figures I just presented are extremely important to keeping Floyd properly hydrated. For most individuals, a fluid loss that is equal to 5 to 10% of their body weight is enough to cause signs of heat exhaustion. Although, Floyd has felt fine after long days of training with up to a 7% loss in body weight, to be conservative we make it a goal that while racing he tries not to lose more than 5% of his body weight. Today he just barely made that cut off.

Unlike those first flat stages the clouds and rain that followed the riders for the first week made way for an oppressively bright sun and a heat and humidity combination that is considered to be "high risk" conditions for exercise (Table 2).

The Bottle & Weight Count:

Besides racing today, all of the riders pounded through a whole lot of water bottles filled with the team's typical ice-cold carbohydrate and electrolyte solution. Today Floyd thinks that he drank about 12 bottles while on the bike. He thinks, because when you're going that fast in conditions like today, you're not really counting, just doing.

The last two figures I just presented are extremely important to keeping Floyd properly hydrated. For most individuals, a fluid loss that is equal to 5 to 10% of their body weight is enough to cause signs of heat exhaustion. Although, Floyd has felt fine after long days of training with up to a 7% loss in body weight, to be conservative we make it a goal that while racing he tries not to lose more than 5% of his body weight. Today he just barely made that cut off.

3) Pre-hydrate as much as you can before exercise. One strategy I recommend to riders is drinking an entire water bottle while they are waiting at the line. The extra fluid in their gut serves as a reservoir that helps to delay dehydration. In addition, that extra fluid also creates a bit of a pressure gradient that helps subsequent fluid enter the body faster.

4) Acclimatize to the heat before competing in the heat. This means that you need to pre-expose yourself to heat if you want to be able to handle exercise in the heat. The best way to adapt to the heat is to do short and very intense workouts in the heat that elicit a very high sweat rate. Intensity is a stronger stimulus for adapting to the heat than volume.

5) Stay out of the heat. If the combination of temperature and humidity are in the risky zone, then it's sometimes best to just avoid exercise until it's cooler. In addition, if you have to compete in the heat, it's always best to stay out of the heat for as long as possible before your competition. This will help prevent unnecessary fatigue and actually help your performance.

6) Pre-cool before exercise. Getting cool before exercising in the heat can actually help your performance in the heat for short events (10 to 30 minutes). While I won't say much about it now, stay on the look out for some unique technology Floyd will be unveiling for the final time trial.

Table 1. Floyd's power data for stage 13.

| | Stage 13 | Tour Average | Min | Max |
|------------------------------|--------------|------------------------|------------------|--------------|
| Basic Stats | | | | |

Powerfeed: The Hardest Day Yet

Stage 14: Now, it's not necessarily about who can produce the most power, but who can hold on to the most power over the rest of the race

By Allen Lim PhD

Route: Adge to Ax-3 Domains
Type: Mountain Stage
Distance: 220.5 km or 107.6 miles
Elevation Change: 1,359 meters or 4,459 feet gain (Average pt to pt grade = 0.61%)
Total Feet Climbed: 3,209 meters or 10,529 feet
Average Elevation: 440 ? 474 meters or 1,444 ? 1,554 feet above sea level
Minimum Elevation: 13 meters or 43 feet
Maximum Elevation: 2001 meters or 6,565 feet
Weather: 85°F to 92°F and 35 to 70% Humidity. Another hot and dangerous day.

Climbs:

1. Col de Villerouge (Cat 4): 6.3 km at 3.6% beginning at 84 km point.
2. Col de Bedos (Cat 4): 3.3 km at 4.4% beginning at 95 km point.
3. Col des Fourches (Cat 4): 2.2 km at 4.5% beginning at 102 km point.
4. Col du Paradis (Cat 3): 5.8 km at 4.1% beginning at 109 km point.
5. Port de Pailheres (HD): 15.1 km at 8.1% beginning at 176 km point.
6. Ax-3 Domains (Cat 1): 7.9 km at 8.3% beginning at 212 km point.

At a Glance:

Stage Placing: 6th
GC Placing: 6th
Time: 05:45:14 (1 min & 31 seconds down on winner Georg Totschnig)
Average Speed: 38.3 km/hr or 23.8 mph
Average Power: 262 Watts
Total Work: 5,427 Kjoules
Stress to Strain Index: 1.72

Big Day:

By all accounts today was the hardest day of racing in the Tour. So far this was the longest day on the bike (5:45 hr:min), the most work (5,427 Kjoules), the most time at race pace intensity (50 min), and the most time at an endurance intensity (115 min) range for Floyd. Most importantly, Floyd gave the overall race his highest perceived exertion rating of 8.5 and 10's for the final two climbs up Pailheres and Ax-3 Domains. Everyone was at their limit on the last climb and as Floyd put it, "racing just doesn't get harder than that." With an even harder stage 15 to come, I don't think there will be that much room for negotiating GC spots after the riders finish tomorrow. As hard as today was, it is worth noting that the power outputs on the final climbs in today's stage were not greater than what Floyd has accomplished in training in the recent past. The difference is that we are now two weeks into racing. Add the heat, stress, and the fact that everyone is getting tired and you have a situation where results are not necessarily about who can produce the most power, but who can hold on to the most power over the course of the race.

At this point, it would be difficult to imagine that we will see any new highs for peak power output. In fact, outside of the increased work and time spent in the two intensity zones mentioned earlier, today's data, while greater than average, is by no means the best of the Tour despite today being the hardest.

Climbing and Cadence:

There are two ways to produce more power on a bicycle. You can either push harder or pedal faster (i.e., increase torque or increase your rpm). The age-old question has been, which of the two is easier or more efficient. The short answer is that if you want to produce more power, you need to do both. That's because, as we increase our power output, how hard we can push tends to plateau, so very high power outputs tend to be more efficient or associated with higher cadences. At the same time, the primary difference between a professional cyclist and a recreational cyclist is that the professional cyclist can simply push harder. They don't necessarily just pedal faster all the time. In fact, for most cyclists, regardless of their fitness, there is almost no detectable change in efficiency at a cadence between 80 to 100 rpm. Although much is often made between the cadence difference of Lance Armstrong and Jan Ulrich, they are simply on either end of that neutral cadence range and when riding side by side up a steep climb they're both producing nearly equal and extraordinarily high power outputs for their body weight.

Thus, the real key to climbing and cadence isn't necessarily pedaling at a particular cadence. It's about having the gears so that regardless of terrain, you can keep your cadence in a neutral range of 80 to 100 rpm. It's also about finding out what works best for you as an individual. Experimenting with a power meter while riding up steep grades is the most objective way to figure that out. At a constant power output simply try changing your gears so that you ride that power output at different cadences. You'll be surprised that you can actually feel that there is a difference in how hard it feels to hold that same exact power output at different cadences. Practically speaking, whichever cadence feels the best for you is probably the one you should go with.

In general, I find that most riders are simply over geared for the hills. The reality is, most bikes sold today are geared for professional cyclists not your average Joe or competitive amateur. After all, the fact that a pro's bike here in the Tour has the same gearing as that sold in your local bike shop should raise some questions. I mean, ego aside, you wouldn't use the same transmission on an engine that is only half as powerful. So for most cyclists, instead of the standard tooth crank combination of 53 x 39, I recommend a "compact crank" combination of 50 x 34. For the everyday cyclist, it just works better because it helps keep you in that normal cadence range on steep climbs. But if you're not ready to let go of those big chain rings, then it might interest you to know that in tomorrow's stage - the hilliest of all the Tour stages - Floyd and his teammates will be going "compact." In the end, it's not about pride it's about speed.

Table 1. Floyd's power data for stage 14.

| | | Stage 14 | Tour Average | Min | Max |
|-------------------|------------------------------|--------------|-------------------------|------------------|---------------|
| Basic Stats | Duration (hrs:min) | 5:45 | 4:32 ± 0:37 | 3:43 (S13) | 5:45 (S14) |

Powerfeed: Fighting Fatigue

Stage 15: Finding your limit is the best thing possible

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Sunday, July 17th

Route: Lezat-sur-Leze to Saint-Lary-Soulan

Type: Hardest Mountain Stage on Paper

Distance: 205.5 km or 127.4 miles

Elevation Change: 1,475 meters or 4,839 feet gain (Average pt to pt grade = 0.72%)

Total Feet Climbed: 4,869 meters or 15,975 feet

Average Elevation: 783 ± 428 meters of 2,570 ± 1,403 feet above sea level

Minimum Elevation: 205 meters or 673 feet

Maximum Elevation: 1,680 meters or 5,512 feet

Weather: 86°F and 55% Humidity. The heat is still oppressive and the sun garish. But not as bad as yesterday.

Climbs:

1. Col de Portet-d'Aspet (Cat 2): 5.9 km at 6.9% beginning at 89.1 km point.
2. Col de Mente (Cat 1): 7 km at 8.1% beginning at 93.5 km point.
3. Col du Portillon (Cat 1): 8.4 km at 7.3% beginning at 129.1 km point.
4. Col de Peyresourde (Cat 1): 13 km at 7% beginning at 149 km point.
5. Col de Val-Louron-Azet (1): 7.4 km at 8.3% beginning at 182.1 km point.
6. St. Lary Soulan (HC): 10.3 km at 8.3% beginning at 195.2 km point.

At a Glance:

Stage Placing: 19th

GC Placing: 7th

Time: 06:16:12 (9 min & 34 seconds down on winner George Hincapie)

Average Speed: 32.8 km/hr or 20.3 mph

Average Power: 249 Watts

Total Work: 5,620 Kjoules

Stress to Strain Index: 2.01

Looking Ahead:

We all knew that today was going to be a difficult and decisive day. I haven't had a chance to catch up with Floyd in depth yet, but I know he gave it his all. Unfortunately, he had a mechanical problem on the final climb and had to switch bikes. It cost him some time, but that's bike racing. If anything, it looks like Floyd will finish this race in the top ten and while I know he expected more from himself, every day of this Tour has been an invaluable learning experience and I couldn't be more proud of what he's accomplished so far.

With the power data we've already collected, we've gained some clear-cut knowledge about ways we can improve his preparation and race for next year. But in the short term, it's time to really start thinking about the final **individual time trial**, to get some well-deserved rest tomorrow, and to look for every opportunity to move forward over this last week. Today may have been the hardest day in the Tour, but the race is far from over and this last week is going to be a difficult one.

The Numbers:

In short, today we saw the most time (6 hrs & 16 min), most work (5,620 Kjoules), highest rating of perceived exertion (10 out of 10), most work based on perceived exertion (11,286 Kjoules), highest stress to strain index (2.01), most time at lactate threshold (69 min), the slowest speed (20.3 mph), and surprisingly, the most time at zero watts (54 min).

In addition, we did not see any new highs for peak power output. Though Floyd's peak power values were, for the most part, all above average, they were not nearly as close to the high power outputs we saw in the earlier mountain stages. As Floyd explains it, at this stage of the game, all of the riders have pretty much unloaded their peak efforts. Now there's just one sustainable power range to hang on to.

While this isn't exactly true, it is interesting to see that for the major mountain stages, the time spent in different intensity zones was incredibly consistent. In some ways it does appear that for any given zone, there is a fixed amount of time Floyd can spend in each before cashing out. Of particular interest to me is how similar the time spent at the top end anaerobic or "supra-maximal" intensity zones has been. Interesting, because it's the ability to go in the "red" and follow hard attacks that seems to distinguish Armstrong from GC rivals like Ulrich, Leipheimer, Basso, and Floyd. Anecdotal and theoretically, it's been said that only the truly aerobic based riders can win the Tour as they are the ones who, while not having the highest peak power outputs, are the ones who fatigue the least and who are able to sustain consistently high power outputs over many hours and many days.

In the Armstrong era of racing, however, it is clear that the combination of an incredible aerobic capacity and an extraordinarily unique ability to accelerate into very high "red zone" or supra-maximal intensity ranges has been a fundamental aspect of Armstrong's victories. While every racer intuitively understands that if they spend too much time in these very high intensity ranges that their day could be over before it even starts, it's unknown how much training can push this fixed limit back, if improving anaerobic capacity inhibits one's aerobic capacity (or vice versa), or if all of these attributes are simply genetically fixed. Whatever the answer, the very small variability in the supra-maximal data we've collected so far does highlight that some sort of limit has been consistently reached in this year's Tour. For us, finding limits is the best thing possible because you can never push back what you can't see.

Causes of Fatigue:

While I'm on the topic of rate limiters and since I've already talked a bit about how fatigue at this stage of the Tour may have put a cap on peak power outputs, I thought

GDC00824

I'd talk a little bit about what causes fatigue. In effect, what are the different mechanisms or reasons for why we get tired when we exercise?

1. Accumulation of Metabolic Product:

If we're talking about high intensity exercise, or all out exercise lasting for seconds to minutes, the primary reason for fatigue is the accumulation of metabolic products - namely lactic acid.

Our bodies have two basic ways of making energy - aerobically (oxidative) by burning fat, carbohydrate, and sometimes protein with oxygen or anaerobically (non-oxidative) by breaking down stored carbohydrate in muscle without oxygen.

Whether we produce energy using oxidative or non-oxidative energy pathways is not necessarily dependent upon whether oxygen is or isn't present. Rather, it's dependent on our power output or how quickly we need energy (i.e., the relative exercise intensity). This is because non-oxidative energy pathways have significantly fewer steps and thus can produce a limited amount of energy extremely fast. Think of it as the fast lane in Germany (This analogy wouldn't work in the U.S.). You can only stay in that lane for very short periods of time before moving over but while you're in that lane you're hauling.

Unfortunately, hauling in the fast lane has a negative consequence in the form of lactic acid accumulation. That is, whenever you produce energy anaerobically (and you're almost always producing at least some of your energy anaerobically when exercising), your body produces lactic acid as the by-product. In most cases, your body is always producing and removing lactic acid, but when you're redlining your body can't remove that lactic acid as fast as it's made. As a result, the acid associated with the lactate (lactate in and of itself does not cause fatigue) can quickly build up and actually inhibit muscular contractions as well as cause the sensation of pain (i.e., "The Burn") in working muscle. What is interesting and what I alluded to earlier is that there seems to be a fixed number of times you can "pass" in the fast lane before that entire lane just shuts down and you're forced to retreat to that slow moving but ever consistent "long haul trucker speed." I don't know the answer to this but the answers could be related to how the accumulation of lactic acid or other metabolic waste products effect some other variables listed below.

2. Depletion of Substrate:

The flip side of accumulating a metabolic by-product that causes fatigue is running out of metabolic substrates or fuel. In short, if the fumes don't get to you first, you'll probably run out of gas later. The type of gas that is the most critical rate limiter is carbohydrate, especially the carbohydrate stored in working muscle in a form we call glycogen.

Though endurance athletes use fat as a primary fuel source and protein can also help to contribute to energy metabolism, fat and protein are essentially unlimited, while glycogen or the carbohydrate you can ingest through your gut is fixed. More importantly, once carbohydrate is depleted, athletes fatigue regardless of how much fat or protein they have in reserve. This is because in normal conditions your central nervous system is fueled entirely by carbohydrate or your blood sugar. So if you've ever "bonked" or "hit the wall" during exercise, it's because you've run out of carbohydrate, your blood sugar has dropped, and your brain and central nervous system are depleted.

Another reason why running out of carbohydrate is so devastating is because the breakdown of carbohydrate is also important to fat metabolism. Thus, when you're out of carbohydrate, your ability to use fat as a fuel is impaired despite the fact that even the scrawny Tour cyclist has ample fat stores to keep him going. The following analogy isn't exactly biochemically correct, but think of it this way. Your metabolism is like a burning candle where carbohydrate is the wick and fat is the wax. If you just burn the wick, it burns hot and it burns fast. If you just burn the fat, all you get is a big waxy mess. But put the two together and you've got a steady flame. Thus, it is sometimes said that, "fat burns in a carbohydrate flame."

For most pros in the Tour, the best way to maintain carbohydrate stores is to eat a high percentage of carbohydrate all the time and to eat a lot of carbohydrate immediately after exercise. While racing, ingesting as much carbohydrate in the form of energy drinks, coke, pastries, gels, candy bars, energy bars, and fruit is critical to keeping the machinery going as the intensities and energy expenditures are so high that there would be no way to ever store enough carbohydrate or glycogen to get any of these cyclists through a single day on the bike here, let alone 21 days. With this in mind, we often say that the most critical asset a Tour de France cyclist has is an iron gut. In fact, it's probably not a stretch to say that for many of these athletes, their gut's (i.e., the small intestine) ability to process and transport valuable carbohydrate and fluid into the body is probably the most critical determinant of fatigue. One final substrate that may possibly limit these cyclists is stored creatine phosphate - a compound important for producing energy anaerobically. Though there is currently no evidence that creatine phosphate loading improves aerobic performance, there is evidence that it can help with maximal strength performance. The unknown question is whether or not more creatine would help with repeated top end accelerations and attacks. My instinct is that it would not, as there are some other potentially negative side effects for endurance athletes loading on too much creatine. But who knows. Maybe it's this substrate or lack of it that shuts down the fast lane.

3. Neural:

When we think about sports, we think of things like our muscles, heart, and lungs as rate limiting our performance. There is good evidence, however, that fatigue in both strength athletes and endurance athletes is not related to those "peripheral" parts, but to the electrical wiring or nervous system that controls it all.

The classic example of this is an athlete wired up with external electrodes who, after reaching a point where his muscles are completely fatigued, is able to do more work when those same tired muscles are externally stimulated with an electrical jolt that mimics our own nervous system. Thus, it may not be our muscles that get fatigued but our nerves. This could be related to something as simple as the balance of sodium and potassium in our bodies that are critical to creating the electrical signal that run down our nerves. Or it could be valuable neurotransmitters that get depleted or lost after a long day of hopping junctions from one nerve cell to another. In fact, there is some evidence that serotonin re-uptake inhibitors - drugs normally taken for depression - can actually help athletic performance by limiting neural fatigue. Finally, I have to mention that the agonizing and completely fatiguing exercise induced muscle cramp may indeed be a neural issue. Of course, this could be directly related to how electrolytes like sodium and potassium control nerve impulses. However, it's probably more related to that simple "knee jerk" reflex that occurs when a doctor taps your knee with that little hammer. Inside each muscle is a very small set of fibers called intrafusal fibers that tell your nervous system whether your muscle is shortening or lengthening. It's this delicate fiber that gets stretched when your knee is hit with the doctors hammer and which sends a reflex signal through your spine that makes your quad contract. It's theorized that these little intrafusal fibers fatigue before the larger muscle fatigues, thereby causing an electrical storm that causes an uncontrolled muscle cramp.

4. Endocrine:

Over the course of many days of hard training or racing like the athletes are facing here, it is common if not inevitable that our endocrine system actually fatigues. That is, the hormonal pathways responsible for producing vital hormones such as testosterone actually get tired and stop producing normal amounts of hormones important for recovery, immune function, and normal health. As an example, this endocrine fatigue is thought to be a major player in the bone loss and loss of menstrual cycle in many elite female endurance runners. For some professional cyclists we know that bone loss is a real and significant health issue. And while they don't lose their menstrual cycle, they do lose their libido. Just ask their wives.

5. Heat Load:

In the last few days, this had to be a major factor causing fatigue in many of the cyclists. In fact, over heating and becoming dehydrated is a factor in performance that just can't be ignored. So have a drink and stay cool cause there's still one more week of hard racing left to go.

Table 1. Floyd's power data from stage 15.

Powerfeed: Lost Computer

Stage 16: The PowerTap took a flyer, leaving Floyd riding commando

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Mourenx to Pau
Type: Mountains with Flat Finish
Distance: 180.5 km or 112 miles
Elevation Change: 98 meters or 322 feet gain (Average pt to pt grade = 0.05%)
Total Feet Climbed: 2,392 meters or 7,848 feet
Average Elevation: 783 ± 428 meters or 2,570 ± 1,403 feet above sea level
Minimum Elevation: 112 meters or 367.5 feet
Maximum Elevation: 1,709 meters or 5,607 feet
Weather: 78°F and 69% Humidity

Climbs:

1. Col d'Ichère (Cat 3): 4.4 km at 6.2% beginning at 46.1 km point.
2. Col de Marie-Blanche (Cat 1): 9.3 km at 7% beginning at 61.2 km point.
3. Col d'Aubisque (Cat HC): 16.5 km at 7.2% beginning at 92 km point.
4. Cote de Pardies-Pietat (Cat 4): 2.6 km at 5.2% beginning at 158.4 km point.

At a Glance:

Stage Placing: 44th
GC Placing: 8th
Time: 04:42:04 (3 min & 24 seconds down on teammate Oscar Pereiro)
Average Speed: 38.6 km/hr or 23.9 mph
Average Power: Floyd thinks maybe 230 to 240 Watts
Total Work: 3,976 Kjoules based on Floyd's guess
Stress to Strain Index: 1.60
Today's Race:

After Sunday Oscar Pereiro was fired up to go out on the attack again today. He was so fired up to make something happen and rode what I think is one of the most incredible races ever. The team was in an emotional frenzy when he crossed the line. It was pretty cool.

Today's Power Data:

The computer fell off the bike. It's embarrassing to say, but that's what happened. About 10 km from the line through a really bumpy section of road, the computer came loose from the bracket and the next thing Floyd knew he was riding commando style. We thought about going back to get it, but as the saying goes, "when your keys fall in molten lava, you just need to let them go...just let them go."

And so, I guess for today, that's exactly what I have to do. It's a serious bummer for both Floyd and myself, because the climbs on today's stage were hard. He says that on the last 3 km of the Col de Marie-Blanche there were consistent 12% pitches. He also thinks there could've been some new peaks for the 5 to 10 minute range, but beyond that everything, at least for the climbing, was really similar to the previous stages. So we're going to go back later and look at video of the climbs and based on the ascent rates, back calculate the average power for the climbs. How we are going to do this is actually pretty interesting.

Yesterday I got to meet the owner of Mat Sport Timing. He operates the photo finish system here at the Tour and came to us because he's been seeing Floyd cross the line everyday with the PowerTap and was really stoked that he was doing the entire Tour with it (He gave me some pictures of Floyd crossing the line in this article). Anyway, he's hooking us up with a system that searches the time code on the video here at the Tour. It will allow us to sync the clock on the PowerTap to the exact time in video. Not only will we be able to search today's data, and based on the course map make some invaluable assessments of the day, but we'll also be able to go back and see what was going on for any given piece of power data. I guess that makes me feel a little bit better about the PowerTap computer getting launched today.

©Allen Lim

Other Thoughts:

I was going to search Floyd's power data today with a specific bent on examining whether there are any signs of over-reaching and over-training in his data from the last few months. Since the data took a flyer, my brain sort of followed, so I'll save any deep thoughts on that topic for tomorrow. Until then, I'll leave you all with a controversial teaser. There is no such thing as overtraining...just under-resting.

Powerfeed: A Stage Filled With Contrast

Stage 17: The longest stage of the Tour produces one of the lowest power outputs

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Pau to Revel
Type: Flat with some rollers
Distance: 239.5 km or 148.5 miles
Elevation Change: -2 meters or -7 feet loss (Average pt to pt grade = -0.001%)
Total Feet Climbed: 1,042 meters or 3,419 feet
Average Elevation: 289 ? 61 meters of 948 ? 201 feet above sea level
Minimum Elevation: 185 meters or 607 feet
Maximum Elevation: 407 meters or 1,335 feet
Weather: 84°F and 48% Humidity

Climbs:

1. Cote de Baleix (Cat 3): 1.6 km at 7.1% beginning at 19.9 km point.
2. Cote de Betbeze (Cat 4): 2.2 km at 6.4% beginning at 86.3 km point.
3. Col d'Aubisque (Cat 4): 1.8 km at 4.9% beginning at 157.7 km point.
4. Cote de Pardies-Pietat (Cat 3): 2.7 km at 5.1% beginning at 229.7 km point.

At a Glance:

Stage Placing: 33rd
GC Placing: 9th
Time: 06:16:12 (22 min & 48 seconds down on winner Paolo Savoldelli)
Average Speed: 39.5 km/hr or 24.5 mph
Average Power: 198 Watts
Total Work: 4,326 Kjoules
Stress to Strain Index: 1.26

Wind Up:

This was a strange race day. I guess you could say it was filled with a lot of contrast. At only 198 watts, it was Floyd's lowest average power output for the entire tour. It was, however, the longest race of the Tour at 148.5 miles and one of the longest at just over 6 hours for Floyd.

Initially, I thought that the low average power output was due to a combination of the duration and the relatively flat roads. Generally speaking, the longer the race the lower the power output. And as we saw from the flat stages in the **first week**, the tremendous savings from drafting can really drop the average power output. To see if this was the case, I broke down the race by each hour and found something pretty interesting. In the first hour, Floyd's average power output was 259 watts, the second hour was 168 watts, the third hour was 170 watts, the fourth hour was a measly 141 watts, the fifth hour was 175 watts, and the last hour was 272 watts. Over the last hour, the first quarter (5:00 to 5:15) of that hour was 207 watts, the next 15 minutes (5:15 to 5:30) was 251 watts, the next 15 minutes (5:30 to 5:45) was 257 watts, and the final 15 minutes (5:45 to 6:00) was an amazing 371 watts.

Based on this information, the low average power output really had nothing to do with the length, it was largely dictated by extremely low wattage in the middle of the race. In fact, there was so much floating in that middle section that over the course of the race, Floyd rode at zero watts for 84 minutes.

Essentially, these guys ripped the first hour, did nothing for the next 4 hours, and then ripped it for the last hour. Actually, they really put it down for the last 30 minutes. In fact, over the last category climb, Floyd sustained a power output of 474 watts for 5 minutes. That's only 4 watts less than the best he was able to hold on stage 9. So nobody was holding back on that climb.

Unfortunately, Floyd found himself a little too far back on that climb and got gapped. It won't happen again.

Table 1. Floyd's power data for stage 17.

Powerfeed: Exceeding The Limits

Stage 18: The culture of the Tour is to yearn for more than what was ever thought possible.

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Albi to Mende

Type: Climb, descend, climb, kinda flat, climb, rollers, hard climb to finish.

Distance: 189 km or 117.2 miles

Elevation Change: 868 meters or 2,848 feet gain (Average pt to pt grade = 0.46%)

Total Feet Climbed: 2,108 meters or 6,916 feet

Average Elevation: 644 ± 252 meters or 2,112 ± 827 feet above sea level

Minimum Elevation: 182 meters or 597 feet

Maximum Elevation: 1,084 meters or 3,557 feet

Weather: 77°F, clear, and 50% Humidity

Climbs:

1. Cote de la Bessede (Cat 4): 8.3 km at 2.9% beginning at 44.7 km point.
2. Cote de Raujolles (Cat 3): 2.7 km at 5.2% beginning at 96.3 km point.
3. Cote de Boyne (Cat 2): 9.2 km at 5.3% beginning at 121.3 km point.
4. Cote de Chabrits (Cat 3): 1.7 km at 7.1% beginning at 178.3 km point.
5. Cote de la Croix-Neuve (Cat 2): 3.1 km at 10.1% beginning at 184.4 km point

At a Glance:

Stage Placing: 20th

GC Placing: 9th

Time: 04:49:43 (12 min & 7 seconds down on winner Marcos Serrano)

Average Speed: 39.1 km/hr or 24.3 mph

Average Power: 222 Watts

Total Work: 3,859 Kjoules

Stress to Strain Index: 1.91

Tired:

The riders came across the line looking tired today. It's kind of strange how you don't notice the really subtle changes that occur each day. But this race has been wearing on the athletes from day one and for whatever reason you could just see it across the peleton as they came up the final climb today. They look noticeably thinner, haggard, quieter, and more direct with their actions - as if realizing that every movement is a precious use of energy.

The Climb:

And yet, on that last climb the very physics of movement have left me in awe. Today, after 17 days of racing, and 184.4 km into this stage, Floyd came up the 3.1 km Cote de la Croix-Neuve in 10 minutes and 16 seconds. At a grade of 10.1% he climbed that hill at a VAM or rate of ascent of 1823 meters per hour averaging 11.2 mph. That is like climbing just over one vertical mile (1.13 miles) or well past Boulder, CO from sea level in one hour. Based on the physical climbing rate, the math says that Floyd would have needed to produce 430 watts to climb that fast. In fact, isolated and riding alone, he averaged exactly that - 430 watts or 6.46 watts per kg. This is only 5 watts less than Floyd's highest 10-minute peak power of 435 watts that occurred on stage 8 during the last part of the final climb into Gerardmer, where riders were fresh and chomping at the climbing bit. If you think any of this is impressive then consider this, Floyd got dropped.

Possibilities:

A climb like today's is a real great one for us to analyze. Based on the power numbers from Floyd's PowerTap and the confirmation of those values against basic physics and math, we can get a nearly exact understanding of what Floyd would have needed to do to stay with the Yellow jersey group. To make up the approximately 30 second gap that the others had on Floyd over the top, Floyd would have needed to produce about 5% more power or 24 watts extra for a total of 454 watts. That would put him at a power to weight ratio of 6.78 watts per kg, a VAM of 1920 meters per hour, and a speed of 11.7 mph.

So there you have it. We just found another line and another goal. It is in my experience, what could be at the very limit of human possibility. But that's the culture of the Tour - to yearn for more than what was ever thought possible.

Powerfeed: Going Wireless

Stage 19: New equipment makes life easier for everyone

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Issoire to Le Puy-en-Velay

Type: Hard Rollers

Distance: 153.5 km or 95.2 miles

Elevation Change: 269 meters or 883 feet gain (Average pt to pt grade = 0.18%)

Total Feet Climbed: 1,491 meters or 4,892 feet

Average Elevation: 823 ± 192 meters of 2,702 ± 631 feet above sea level

Minimum Elevation: 358 meters or 1,175 feet

Maximum Elevation: 1,196 meters or 3,924 feet

Weather: 86°F and 60% Humidity, clear hot skies.

Climbs:

1. Cote des Gerbaudias (Cat 4): 6 km at 3.1% beginning at 17 km point.
2. Col de St. Eloy la Glaciere (Cat 3): 11.3 km at 3.2% beginning at 27.2 km point.
3. Col des Pradeaux (Cat 2): 11.4 km at 5.6% beginning at 56.6 km point.
4. Cote des Terrasses (Cat 4): 2.9 km at 3.7% beginning at 93.1 km point.
5. Cote de Malaveille (Cat 4): 2.9 km at 5% beginning at 104.6 km point

At a Glance:

Stage Placing: 71st

GC Placing: 9th

Time: 03:37:35 (4 min & 31 seconds down on winner Giuseppe Guerini)

Average Speed: 42.3 km/hr or 26.2 mph

Average Power: 223 Watts

Total Work: 2,911 Kjoules

Stress to Strain Index: 1.79

Sweet Freedom:

A couple of days ago, I ran out of clean underwear and had to make an important executive decision about my options here at the Tour. At the same time, we made a very similar executive level decision about Floyd's Power Tap, going somewhere we've never gone before - wireless. I wanted to keep it quiet for a few days. Get use to it and see how it worked before I made any long-term commitments to the idea. After the last three stages, I must say, the feeling is really incredible and the equipment has never worked better.

That equipment is the CycleOps PowerTap SL 2.4 which features coded digital technology that literally blasts Floyd's power data from hub to handlebar, no strings or wires attached. The computer also features a coded digital heart rate receiver and is USB downloadable. One of the perks of working with Floyd here at the Tour is being the first to access the latest and greatest in technology. Though the new wireless PowerTap has been working great for us now, it won't be available for purchase until early 2006.

On a side note, going wireless really got the team mechanics excited. They are as much about the functionality of the equipment the riders use as the aesthetic. Tearing off that wire, getting rid of that highly visible line on the backside of the bicycle, and showing off the clean tubes of the new BMC bike Floyd is riding with those oh so sexy low top Zipp 202 carbon rims, made them as giddy as a group of 8th grade school boys on a topless beach in Nice. Hmmm...maybe it's time to go home now.

Fast and Furious:

When Floyd crossed the line today, he had this look on his face. It's the kind of look that I'd imagine someone jumping off a plane while trying to figure out a really complex calculus problem would have. Wind blown, wide eyed, and thrilled - all while being utterly confused and perplexed. Though the numbers don't quite show it, today's stage into Le Puy-en-Velay was an impressive one that left Floyd in awe at the strength of his teammates and the peleton. At a rating of perceived exertion of 8 out of 10 for an average power of only 222 watts, today was definitely unique. There was just never any let up on a course that was much harder than it appeared on paper.

It wasn't so much the speed as the consistency of the pace and the never-ending undulations in terrain that made this stage hard. Based on the course profile map given to the riders by the Tour organization there was a total of 4,892 feet of total climbing listed on what was this year's second shortest road course. Every day, I've been asking Floyd to confirm that number using his own internal barometer, and he swears that there had to be at least 8,000 feet of climbing today. On the big mountain stages, his intuition was always within 500 feet of the actual, and so I have no reason to believe he's too far off. What the course maps just don't list are the hundreds of small little rollers that can add up and really make a day harder than expected.

Other factors that were major players in today's race included the heat and the accumulated strain of racing for almost 3 weeks. I wouldn't call it fatigue. I'd call it "when is this race ever going to end?" Floyd would call it "I just want to have an ice cold beer and a burrito in my own backyard." Whatever you want to call it, it didn't have a large effect on the power numbers from today. We had new lows for total time and distance and a surprising new low for Floyd's 5-second peak power (731 watts). Though there were also new lows for time spent at his endurance zone and supra-maximal zone, they really just reflect the lower overall time as the percent time spent in different zones is very similar to the Tour averages.

Health vs. Performance:

One thing I've been thinking a lot about lately as I watch these guys perform at super-human limits is literally how insane all of this is. Don't get me wrong, I'm as

GDC00832

impressed and inspired as the next guy at what these athletes are able to do. It's just that elite athletic performance is not necessarily synonymous with good health or wellness. As we get close to the end of this year's Tour, I think it's really important to emphasize that the numbers I've been broadcasting are truly bizarre and at the top end of what the human body should or can be asked to handle. As a point of reference, the Surgeon General defines "Physical Fitness" as, "the ability to carry out daily tasks with vigor and alertness, without undue fatigue, and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies." Furthermore, to be physically fit, the Surgeon General recommends that the average American, accumulate 1500 Kcal or Calories (approximately 1350 Kjoules) of physical activity per week. This means, that we should be doing things like walking, cycling, mowing the lawn, lifting weights, and jumping up and down to the extent that we burn 1,500 Calories doing so each week. It doesn't necessarily matter if we do that for 30-minutes each day, for 1-hour every other day, or at low or high intensities. It just matters that we do it.

As an example, a normal person will burn 100 Calories for every mile they walk. To walk a mile you need to take about 2,000 steps. So if you walked, 5 miles a day or 10,000 steps 3 times per week, you'd be at the recommended 1500 Calories. If you walked just over 2 miles a day, every day, you would be close to the Surgeon General's recommendation. The bottom line is, it doesn't take a lot of physical activity to be physically fit. Just walk more.

If you compare that 1,500 Calorie or 1350 Kjoule recommendation for cycling with Floyd's average day of 4,013 Kjoules here at the Tour de France, then you start to see how extreme this bike race is. At an average of 4,000 Kjoules a day, over a week, Floyd would have accumulated 28,000 Kjoules of exercise. That's almost 19 times more than what is recommended by the Surgeon General. Based on the numbers, I wouldn't exactly say what he's doing here is healthy.

Comparing how Floyd feels on most days relative to the Surgeon General's definition of physical fitness is another story. For the most part, when he's not racing his bike, he's not exactly the poster boy for carrying "out daily tasks with vigor and alertness." And if we're talking about "undue fatigue" then all of these guys are hurting. Finally, if anyone thinks that Floyd or any of his teammates has "ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies" at this year's Tour, then they are out of their mind.

In fact, being this physically fit is in no way healthy. The Surgeon General defines "Health" as the, "capacity to enjoy life and to withstand challenges. It is not merely the absence of disease." With that in mind, the question, "are we having fun yet" is really an important one. If I was racing, my answer would be, "maybe...if I wasn't on a mostly liquid diet, trying to burn more calories than a toaster oven left on high all day, all while navigating unknown roads at terrorizing speeds." Add to that the significant bone loss faced by many of these cyclists, the significantly impaired immune function from the stress of exercise and travel, their overdrawn hormonal systems, and the various musculoskeletal aches, pains, and injuries sustained during this race and healthy becomes the last word I'd use to describe a Tour rider.

Ultimately, the bottom line is you don't have to train for or ride in the Tour de France to be Physically Fit and Healthy. If anything not doing the Tour almost insures that you are physically fit and healthy. In the end, the value of something like the PowerTap technology and monitoring everything we monitor here at this race lies in helping to improve the quality of lives of every day individuals. The numbers here may be extreme, but tracking your own numbers and being disciplined about your own health and well-being shouldn't be. One thousand five hundred Calories a week. That's all it takes.

Table 1. Floyd's power data for stage 19.

| | Stage 19 | Tour Average | Min | Max |
|-------------------|------------------------------|--------------|--------------------------|------------------|
| Basic Stats | Duration (hr:min) | 3:38 | 4:52 ± 0:47 | 3:38 (S19) |

Powerfeed: The Classic

Stage 20: Tour riders are a class in themselves

By Allen Lim PhD

Here's the latest installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Saint-Etienne to Saint-Etienne

Type: Individual Time Trial

Distance: 55.5 km or 34.4 miles

Elevation Change: -3 meters or -10 feet loss (Average pt to pt grade = -0.01%)

Total Feet Climbed: 619 meters or 2,031 feet

Average Elevation: 625 ± 145 meters or 2,049 ± 475 feet above sea level

Minimum Elevation: 475 meters or 1,558 feet

Maximum Elevation: 834 meters or 2,031 feet

Weather: 79°F and 34% Humidity

Climbs:

1. Col de la Gachet (Cat 3): 5.7 km at 4.5% beginning at 34.3 km point.

At a Glance:

Stage Placing: 6th

GC Placing: 9th

Time: 01:13:48 (2 min & 2 seconds down on winner Lance Armstrong)

Average Speed: 45.1 km/hr or 28.0 mph

Average Power: 379 Predicted Watts based on speed, terrain, and drag

Total Work: 1678 Predicted Kjoules

Stress to Strain Index: 1.32

The Time Trial:

All I can say, is those guys went fast. After three weeks of some incredible racing, I am once again in awe at how much power these athletes can produce. With a 6th place finish in today's stage and a top ten GC almost all wrapped up, Floyd is really happy with his performance. He gave it his all and powered to an incredible finish. It's a really great start and an even better learning experience for the future. The bar has been set and we intend to reach the mark.

As for today's time trial, I did a bit of modeling again to predict what Floyd's power output needed to be for his time, the terrain, and the current conditions. I also decided to model a "what if." What if Floyd had the same time as the 5 riders ahead of him? What would his power be? For the 1:13:48 that Floyd posted, I believe his average power was approximately 379 watts. If Floyd had finished at the same time as Armstrong, his power would've been 410 watts - a whopping 8% better. For the riders just ahead of Floyd, the % difference was not as great with Basso, Julich, and Vinokourov finishing at modeled power outputs that for Floyd would've been 1%, 2%, and 3% better. Like Armstrong, Ulrich seems to be in a class of his own at 7% better than Floyd (Table 1).

| NAME | TIME | FLOYD'S POWER (W) FOR THEIR TIME | % DIFFERENCE IN POWER |
|---------------|---------|---|--------------------------|
| 1. ARMSTRONG | 1:11:46 | 410 | 8% |
| 2. ULRICH | 1:12:09 | 404 | 7% |
| 3. VINOKOUROV | 1:13:02 | 391 | 3% |
| 4. JULICH | 1:13:19 | 386 | 2% |
| 5. BASSO | 1:13:36 | 382 | 1% |
| 6. LANDIS | 1:13:48 | 379 | 0% |

Table 1. Based on Floyd's aerodynamic drag, body weight, and coefficient of rolling resistance as well as today's course profile and environment, the above table shows what Floyd's power output would be for his time and the time of the competitors ahead of him. Thus, the power listed and the % difference in power are not the power outputs for Floyd's competitors but the power outputs Floyd would have needed to do to match their time.

ITT Warm-Up Strategy:

I've been getting a lot of questions about Floyd's warm-up strategy for today's time trial. The reality is that his warm-up isn't really that complex, especially for a longer TT like the one here in Saint-Etienne.

©Allen Lim

Essentially, the mechanics will put Floyd's time trial bicycle on a trainer using a standard clincher-training wheel about an hour and a half before his scheduled start time. They'll put his disc wheel on right before he rolls out to the start.

For a time trial of this length, Floyd will only warm up for about 45-minutes, especially if it's warm out. He tries to finish his warm-up about 15-minutes before the start, so today he was on the bike about an hour before his start. During the warm-up Floyd tries to ride a fairly moderate pace, with maybe 3 to 4 intervals close to but not over his lactate threshold. One thing we've found is that if you go too hard during the warm-up you don't always produce the same kind of power output that you would if you went a little easier. The key is to really warm-up the legs and get comfortable riding the bicycle, not to kill yourself. For that reason, Floyd rarely does any high intensity surges or maximal efforts while warming up. It's all just moderate to somewhat hard with a few efforts just approaching hard. In a typical warm-up Floyd will average 275 watts, with a few efforts in the 350 to 400 watt range.

Today, Floyd was holding a cadence in the 85 to 95 rpm range during his warm-up. Jonathan Vaughters was hanging out with Floyd at the time and suggested that for his next time trial, Floyd try a much higher cadence of 110 to 120 rpm. I asked why, and Jonathan replied that he felt an important aspect to the warm-up was to get the neuromuscular system fired up and that pedaling at a faster than normal rate helped with this. Jonathan has a huge amount of knowledge and instinct in every aspect of cycling and we will definitely be trying his advice for the next TT.

During the warm-up Floyd tries to ride a fairly moderate pace, with maybe 3 to 4 intervals close to but not over his lactate threshold. One thing we've found is that if you go too hard during the warm-up you don't always produce the same kind of power output that you would if you went a little easier. GDC00834

Today, Floyd was holding a cadence in the 85 to 95 rpm range during his warm-up. Jonathan Vaughters was hanging out with Floyd at the time and suggested that for his next time trial, Floyd try a much higher cadence of 110 to 120 rpm. I asked why, and Jonathan replied that he felt an important aspect to the warm-up was to get the neuromuscular system fired up and that pedaling at a faster than normal rate helped with this. Jonathan has a huge amount of knowledge and instinct in every aspect of cycling and we will definitely be trying his advice for the next TT.

The next strategy is to use an ice vest under his jersey during his warm-up. Essentially, it's a vest with an ice-like gel material embedded throughout that we keep in ice water before his warm-up. The ice vest helps to keep his torso really cold. The torso is essentially the radiator of the human body. When blood vessels dilate on your back, hot blood is brought to the skin surface where evaporating sweat can cool it off. By using the ice vest, we actually increase blood flow to his legs, because less blood needs to flow to the back for cooling. This effect actually can last for the first 10 to 30 minutes of the time trial as well, because the cold skin on his torso prevents his brain from regulating his body temperature at a higher than normal temperature which is typically the case during exercise. This means that more blood is allowed to flow to his legs because less blood is needed to keep his body cool. In addition, by keeping his torso cool, he doesn't have to sweat as much during his warm-up helping to keep him hydrated. What a lot of people don't realize is that one of the biggest rate limiting factors in time trial is not just having enough blood for oxygen delivery but having enough blood to keep the engine from over-heating. Once the body over heats it doesn't matter how much oxygen you can consume or how powerful your engine is, because everything just shuts off.

In summary, for Floyd's warm-up we try to get him on the bike an hour before the start. He rides at a moderate to hard intensity, but never goes in the red. We'd like to use a trainer with a more realistic road like feel so we can experiment with higher cadences. And finally, we do everything we can to keep him cool while he's getting hot.

Powerfeed: It's Only The Beginning

Insight into the most challenging endurance event in the world

By Allen Lim PhD

Here's the last installment of our Powerfeed coverage, with detailed reports on Floyd Landis' performance from his power coach, Allen Lim from data collected off the CycleOps Powertap on Landis' bike. Need a **glossary**?

Route: Corbeil-Essonnes to Paris Champs-Elysees

Type: Flat Stage

Distance: 144.5 km or 89.6 miles

Elevation Change: -25 meters or -82 feet loss (Average pt to pt grade = -0.02%)

Total Feet Climbed: 304 meters or 997 feet

Average Elevation: 70 ± 42 meters or 231 ± 138 feet above sea level

Minimum Elevation: 40 meters or 131 feet

Maximum Elevation: 172 meters or 564 feet

Weather: 66°F and 94% Humidity with a light drizzle

Climbs:

1. Cote de Gif-sur-Yvette (Cat 4): 1.5 km at 5.5% beginning at 56 km point.

At a Glance:

Stage Placing: 91st

GC Placing: 9th

Time: 03:40:57 (Same time as winner Vinokourov)

Average Speed: 39.2 km/hr or 24.3 mph

Average Power: 164 Watts

Total Work: 2,174 Kjoules

Stress to Strain Index: 1.22

Today's Stage:

As expected, **today's stage** was one of the easiest of the Tour, scoring the lowest average power output (164 watts), the lowest total work based on power (2,174 Kjoules), the lowest rating of perceived exertion (4), the lowest total work based on perception of effort (2,651 Kjoules), the shortest distance (89.6 miles), and nearly the shortest time (3:41vs. stage 19's 3:38). In addition, today Floyd spent the least amount of time at all intensity zones except zero watts and his recovery zone. It was a day, that I'd take the risk of saying I might have even been able to finish. Well, maybe if I hadn't spent my last three weeks sitting in a car.

While today's stage was the easiest, it wasn't all a walk in the park. Over the last 30 minutes, the power did come up to an average of 263 watts during the finishing circuits. Floyd spent most of that time floating and trying to stay out of trouble. As beautiful of a stage as it was, I guess it was a bit anticlimactic from a power perspective. That said, over the course of this Tour we've gained some incredible insight on an event that I truly believe is the most challenging endurance event in the entire world.

Totals:

Over the last three weeks Floyd raced his bike (including time trials) a total of 86 hours and 26 minutes, give or take a handful of seconds. That's about 29 hours a week, which is close to what he was averaging in the two months before the Tour. Over that time, he rode a total of 2,116 miles. In doing so, he took approximately 443,922 pedal strokes.

At an average power output of 232 watts over those three weeks, he did a total of 70,914 Kjoules of work, burning somewhere around 74,460 Kcals. That's equal to about 143 large McDonalds Fries, 133 Big Macs, or 372 Krispy Kreme donuts. And while that might sound like a lot, compared to the energy we actually use back home, it's barely even a hiccup in the grid. For example, for the total amount of energy that Floyd expended in this year's Tour de France, he could have kept the state of California powered during peak energy usage for only 22.69 seconds, give or take a second. That means if we were able to harness all of the energy from the entire peloton from all three weeks, we might have kept California going for about 1 hour and 11 minutes.

Finally, looking back at where Floyd spent his energy, the short story is that he spent 30% at or above his lactate threshold and 70% below it. In a sense, 30% of his total time was spent at intensities he'd consider hard to all out, and 70% of his time cruising.

In the end, however, we believe it was the time he didn't or couldn't spend at supra-maximal intensities that had the biggest impact on Floyd's Tour. At a total of 234 minutes or 3.9 hours at or above 500 watts, we think that if Floyd was able to spend 10 more minutes (4% more) at that top end, he might have been on the podium.

In any case, we learned and experienced more than we ever expected and couldn't be happier about getting through and being a part of this year's Tour. Thanks for taking the time for reading and learning with us.

Bicycling

Powerfeed PreTour: The Tour From A Human Perspective

A dedicated scientist takes some time out from the numbers to get in touch with the true spirit of the Tour de France

By Allen Lim PhD

It's been over a year and a half now since I first met Floyd Landis. At the time, I was close to finishing grad school. But instead of feeling optimistic about the future, I was bitter, burnt, and broke. My only plan was to leave Boulder and head back to Los Angeles. I figured I could live with my mom for a while - keep her company and help out around the house. Looking for a career or a future was the last thing on my mind. I just wanted to ride my bike, take some time to figure things out, and just be.

Before I had time to pack up, I got a call from David Cathcart, a close friend who also happened to be the director of marketing for CycleOps. He called to tell me that they had just signed a deal with Floyd who was leaving US Postal to ride for Phonak. David wanted to know if I'd be interested in helping Floyd out with a camp he was putting on. Both Floyd and David would be coming through Boulder and they were interested in meeting to talk details. So a week later I found myself meeting Floyd at a local coffee shop listening to an anthology of unsolicited and unfiltered rants that blasted with the energy of a broken fire hydrant. I thought to myself, "are you kidding me, this guys more bitter than I am..., and why am I so bitter."

After Floyd's camp, Robbie Ventura, Floyd's coach asked if I would help with Floyd's training and power analysis. Compared to Floyd, Robbie was like a bouncy-ball that had just been launched from a 20-story building. Robbie beamed with so much positive energy that it was almost inconceivable that he and Floyd could co-exist in the same space. We sat there in Floyd's living room as Robbie translated for us, rallying the troops like we were getting ready for a field trip to the moon. But it wasn't until I heard Floyd say, "hey Al, I think I can win the Tour. What do you think?" that I really started to pay attention. It was the first time in a long time.

By early May, I was on a flight from Denver to Barcelona heading for Girona, Spain to help a former Mennonite from Pennsylvania take on the biggest race in the world. I arrived in Girona worked and with no bags to find Floyd about to feast on a dinner of cereal and gummy bears. I looked at him and he looked at me. I shook my head and he shrugged his shoulders and then I shyly asked, "Is there a market around here?" An hour later we had a dinner fit for Kings or maybe the odd couple - two eggs over pasta with some Spanish version of Ragu on top. It was a better alternative. We ate on the couch in Floyd's dorm size apartment and watched Star Wars, waxing philosophic about the force, dark side, and Luke Skywalker's inherent belief that he was destined for something bigger than the desert of Tatooine.

Maybe it was the setting, but I felt like a freshman in college all over again -- the same fear, hope, and naive confidence about the future and all of its unknown possibilities. For the first time in a long time, I also missed home. It's that feeling you get when you know you have to go but don't want to. I didn't know the language, I didn't know where I was, and I didn't have my luggage. But my bags eventually arrived, I started picking up the local lingo, and over the next month we both began figuring it out. We set up camp in the Pyrenees and I watched Floyd train harder than I've ever seen anyone train in my entire life. Unfortunately, we came short of our expectations at the Tour. It was humbling but I think we both came home better.

This year, things have been quite different. I took a job with Slipstream Sports as the full time sport scientist for the TIAA-CREF Cycling Team run by Jonathan Vaughters. All the hype about "what's next" at the end of last season was driving me crazy and I thought I'd just go help Jonathan with "what's now." At the same time, Floyd was having the early season of his life and with all of the new found attention, the team played a much more active role in his preparation. For the first time, Floyd was running the show and had the respect and care he deserved. So beyond time together in Mallorca for training camp, some wind tunnel testing, the races back at home and the Dauphine, we didn't get the same quality time roughing it in the Pyrenees like we did last year. Coming back to the Tour this year, I've found myself sentimental for what seems like a whole other era. Perhaps it's that sentiment, that has me looking ahead at this year's Tour with a different perspective. It's the human perspective on the facts and figures that I slaved over at last year's Tour. Although my job this year includes daily power analysis for Floyd and additional teammates who will be riding the PowerTap, I've come to learn over the years that it's not the numbers that makes you good. There's so much more. So in between the average power outputs, the time spent in different zones, peak power outputs, and calculations of ascent rates, I want to try and share more of the human and daily stories that drive this team and all of the individuals associated with it.

Today, Floyd, Robbie Ventura, and J  se Bartholomew who will be my power analysis assistant went for a ride to check out the prologue course. As we started rolling out, Floyd started to sing some tunes by Kid Rock. It put a smile on all of our faces. I looked at Floyd and he laughed and I thought, "wow, this guys going to win the Tour de France."

Bicycling

Powerfeed Prologue: The Average Guy

Riding the prologue course with Floyd Landis puts power in perspective

By Allen Lim PhD

Everyone always asks if I get to ride a lot while I'm at the races and my basic answer is, never. But this year, Jesse Bartholomew, Robbie Ventura, and I all decided to bring our bikes to the Tour. Although our job is to help Floyd ride as fast as he can each day, we figured that between the three of us, we could at least motivate each other to find the occasional hour to get out on the bike. So when Floyd asked us to meet him to pre-ride the prologue course again this morning, we immediately began making plans for the big day.

All week long we've been playing odd-ball games. From naming lines in movies to seeing who can lose the most weight after using the bathroom, our techniques for passing the time span from benign to pretty stupid. And despite the fact that Floyd is a world-class athlete leading a team in the Tour de France, we still like to imagine that we can compare or even compete with him. Basically, when you get us all together we're like a bunch of kids trying to trump the other with the latest "high score." So this morning the goal was to see who could put out the biggest one minute power effort on the prologue course. And with oddly deluded reasoning we thought we could make things fair by just normalizing to body weight. On the elevator ride down from our rooms, we all made our "your mama" predictions. Floyd laid claim to 700 watts and we all just swaggered with confidence like that was a little number. We played it cool, thinking, "whatever man, bring it on."

We took the first lap pretty easy, checking out the best lines through the corners and looking for the smoothest asphalt to cruise over. Floyd got comfortable in his time trial position, letting other riders and teams fly past him as he settled into an easy rhythm, chatting it up with us and humming his favorite tunes. I was feeling good and looking forward for things to get started. Unfortunately, none of us really coordinated exactly when or where we were going to do our effort. And as we came through on the second lap, Floyd decided to open it up a bit. Before we knew what hit us, we were scrambling like we stole something, fighting for Floyd's wheel as if our lives depended on it. I won that battle, but soon realized that there's pretty much zero draft behind Floyd when he's in his time trial position. The first thing I thought was, "oh man, I am screwed." Actually, the person who got screwed was Jesse as I gapped the guacamole out of him. Jesse claims that he wasn't fighting for Floyd's wheel cause, of course, in his words, "there's no freaking draft behind that guy." To his credit, Jesse closed the gap bringing Robbie in tow. I was done, but having got in at least a one-minute effort, I figured I was good for the day. Robbie then came around Jesse giving him some protection and while they both get an A for effort, Floyd eventually sawed them off. I just cruised and waited for him to lap me, which I figured would take less than 8 minutes. After downloading the data, it was confirmed that our best 1-minute effort did indeed occur in that initial dogfight for Floyd's wheel. And, of course, Floyd kicked all of our butts at an estimated 9 watts per kg. I came in at a respectable 6.9 watts per kg, while Robbie and Jesse were tied at 5.8 watts per kg.

Later this afternoon, Floyd's luck wasn't quite as good. While cruising around the start house he got a deep cut in his rear wheel. He decided to play it safe and let the mechanics change it. Unfortunately, his disc wheel doesn't have a quick release and the whole thing turned out to be more of a hassle than expected. Some time was lost at the start, but having still finished in the top ten, we were all glad that he played it safe instead of sorry.

To try and shed some perspective on the day's results and weed out the bad luck at the beginning, I set to work on some mathematical modeling to calculate out the estimated power outputs of his competitors and to also calculate the virtual power outputs for Floyd had he actually won the race. In the top chart attached below, you can see what his competitors achieved and what Floyd actually achieved based on his real velocity (not time). Also in the chart, you can see what Floyd would've had to do to match the winning time. Essentially the difference in time amounts to a 4-watt difference in power output. On today's course that extra 4-watts can come from anywhere. As an example, we estimate that Floyd had to coast for 30 seconds today through the corners. Had he only coasted 26 seconds he would have gained those 4 extra watts. In any case, the math and the actual result give us a lot of confidence. Things happen and we're not losing any sleep over it. Instead we're looking ahead to stage 1 as we've all got bets on how low Floyd can keep his average power in tomorrow's flat stage. In the meantime, Robbie, Jesse, and I will be scheming for more points.

ESTIMATED POWER OUTPUTS FOR TOP 10 IN PROLOGUE:

| Name | Time | | Speed | | Moving Power | Peddalling Power |
|----------------------|------|-------|-------|-------|--------------|------------------|
| | Min | Sec | km/hr | mph | Watts | Watts |
| 1 Thor Hushovd | 8 | 17.00 | 51.43 | 31.89 | 487 | 519 |
| 2 George Hincapie | 8 | 17.73 | 51.35 | 31.84 | 460 | 490 |
| 3 Virtual Floyd | 8 | 18.26 | 51.30 | 31.81 | 435 | 463 |
| 4 Dave Zabriskie | 8 | 21.21 | 51.00 | 31.62 | 434 | 462 |
| 5 Sebastian Lang | 8 | 21.80 | 50.94 | 31.58 | 460 | 490 |
| 6 Alejandro Valverde | 8 | 21.92 | 50.92 | 31.57 | 419 | 445 |
| 7 Stuart O'Grady | 8 | 21.93 | 50.92 | 31.57 | 440 | 468 |
| 8 Michael Rogers | 8 | 23.30 | 50.78 | 31.49 | 453 | 482 |
| 9 Paolo Savoldelli | 8 | 25.02 | 50.61 | 31.38 | 425 | 452 |
| 10 Real Floyd | 8 | 26.26 | 50.49 | 31.30 | 425 | 451 |

ESTIMATED POWER OUTPUTS FOR FLOYD IN EACH DIFFERENT TOP 10 PLACINGS:

| Name | Time | | Speed | | Moving Power | Peddalling Power |
|---------------|------|-------|-------|-------|--------------|------------------|
| | Min | Sec | km/hr | mph | Watts | Watts |
| 1 Floyd 1st | 8 | 17.00 | 51.43 | 31.89 | 438.4 | 467 |
| 2 Floyd 2nd | 8 | 17.73 | 51.35 | 31.84 | 436.6 | 465 |
| 3 Floyd 3rd | 8 | 18.26 | 51.30 | 31.81 | 435.3 | 463 |
| 4 Floyd 4th | 8 | 21.21 | 51.00 | 31.62 | 428.3 | 456 |
| 5 Floyd 5th | 8 | 21.80 | 50.94 | 31.58 | 426.9 | 454 |
| 6 Floyd 6th | 8 | 21.92 | 50.92 | 31.57 | 426.6 | 454 |
| 7 Floyd 7th | 8 | 21.93 | 50.92 | 31.57 | 426.6 | 454 |
| 8 Floyd 8th | 8 | 23.30 | 50.78 | 31.49 | 423.4 | 450 |
| 9 Floyd 9th | 8 | 25.02 | 50.61 | 31.38 | 419.5 | 446 |
| 10 Floyd 10th | 8 | 26.26 | 50.49 | 31.30 | 416.7 | 443 |

Powerfeed Stage 1: Break it Down

When you sit down and try to figure out how to win the Tour de France, the first thing you realize is that you can't really look at it as a three-week race

By Allen Lim PhD

Our guess is that at this year's Tour there will, hopefully, only be eight days in the pain cave, thirteen days at medium heat, and three days just riding bikes. Of those eight hard days, two will probably occur in the first week (Sun to Sat), two in the second week, and four in the last week. The only problem with those four days in the last week is that by the time you get that deep into the cave, everyone's flashlight is dimming and it's unlikely you'd find a spare battery waiting for you...unless, somebody's already been down that cave, but that's a totally different story.

Of the thirteen medium or average days, seven will likely occur in the first week, four in the second week, and one in the last week. Finally, of the three days of just riding, zero will occur in the first week, one will occur on the first rest day in Bordeaux at the beginning of the second week, and two will occur in the last week - the rest day in Gap and the ride into Paris.

Long story short, we're all just trying to take it easy right now. And that includes the riders. With that in mind, there's really not that much to talk about with respect to the power data, except for the fact that it's taking us more time to break everything down each evening. Unlike last year, where Floyd was the only one on the team who rode the PowerTap each day, the "I want to be cool too" factor has given us four additional riders who will be on power meters this year - Koos Moerenhout, Robbie Hunter, Victor Hugo Pena, and Nicolas Jalabert. In addition, last year nobody on the team except for Floyd was interested in the data, but this year Jesse and I are spending our evenings writing up summary reports for the directors, doctors, riders, and our chef Gisbert (he just likes to be in the know).

Preparing for these reports has been difficult because they need to be detailed enough to give everyone an exact picture of everything that is going on with each rider and the team, while also serving as this team's first introduction to a concerted monitoring process. So deciding on exactly what power data and accompanying information to give the team has been a challenge. Here's what we've settled on:

- 1. Basic stage and general classification information.** This includes finishing time, place, time gaps, distance and speed.
 - 2. Weather Information.** Temperature, humidity, wind, radiation, and heat index measures.
 - 3. Race Notes.** A short summary of what happened and how individual riders felt about the day. This is my favorite thing to read back on when I look at old training diaries.
 - 4. Average Power or Stress.** This is broken down into power when the bicycle is moving versus the power produced when the rider is actually pedaling (i.e., excluding coasting time). Power data is given in absolute terms as a "Watt" and normalized to body weight in "Watts per Kg of Body Weight." In very simple terms, the average power is the average of intensity of the race.
 - 5. Strain.** This is basically a perceived rating of how hard or intense the riders felt the race to be and a measure of the rider's heart rate response - a physiological measure of the intensity of the race. This information is extraordinarily important because with this information and the power information, we have what actually happened from a mechanical or physical perspective (power) and how the athletes responded, from a psychological and cardiovascular perspective.
 - 6. Work Done.** When you take the average intensity and factor in the total time of the ride, you get the total work done or energy expended. Because we draw intensity measures from power, perceived exertion, and heart rate we get work scores for all three that we then normalize to Kjoules - a mechanical measure of work versus the Kcal, which is a thermal measure of work.
 - 7. Work Ratios.** All things being equal, the work done measured with the power meter should match the work measured by perceived exertion (RPE) and heart rate. Generally speaking, if the rider thinks that the ride was a lot harder or easier than it actually was, then the ratio between work measured by power (Stress) vs. work measured by heart rate or RPE (Strain) rises or falls. Looking at these ratios is a lot like looking at the actual temperature versus the wind chill factor or heat index. There's what's actually happening and how you're responding to it and it's that very simple dose-response paradigm that is at the heart of proper training.
 - 8. Power Distribution.** We look at how the power output was distributed each day in three ways. The first is time not pedaling. It's kind of a side competition, but in actuality it's a great measure of how much rest a rider is getting. The second way we look at power distribution is normalized to body weight in increments of 1 watt per kilogram of body weight. From the team's perspective, this will probably be the most important measure on the make or break days as there is an absolute power to weight that a rider is going to have to be able to do to stay with the leaders or win on the climbs. More importantly, if you aren't spending the same amount of time in different power to weight zones as the leaders, you probably aren't near the lead. And if you are spending the same time, as the leaders in these zones but aren't in the lead, you're either a wicked strong super domestique helping a team leader or just a really bad bike racer.
 - 9. Peak Power Output.** We list out the best power output for different time frames ranging from 5 seconds to 1 hour as well as the distance they occurred at so the riders can reference their road maps and see when they pounded big efforts.
 - 10. Surges.** This is a count of how many times a rider spikes above 6 watts per kg, 8 watts per kg, and 10 watts per kg. It's really indicative of how many attacks to place and how unsteady the race was. Generally speaking, training looks like a calm lake compared to the turbulence of a race.
 - 11. Hydration and Energy Status.** We weight the riders before and after each stage and take a count of all the bottles and food they drink. This allows us to figure out their sweat rates, sweat loss, and help give the riders feedback about their drinking needs. By combining this info with the "Work Done" and "Weather" info we can make future predictions about their fluid needs based on the race profile and weather.
 - 12. Climbs and Special Features.** In this section we break down exactly what happened on a particular climb or "special" moment. And there are always a lot of special moments. Anyway, we do a mathematical estimate of what should've happened and then compare that with what actually happen. Since all of this analysis is performed relative to terrain, the riders have a deeper frame of reference for those numbers as they all orient to geography when they think about their race. It's never, "when I was doing my best 5 minute effort in my E2 X-Beta Alpha zone." Instead it's something like, "when I was putting the smack down after the left when we passed the van down by the river."
- Despite the depth of these reports, what I'm trying to get at is that during the first week of this race, what we're really hoping to show the riders, and what we are expecting, is that things are pretty normal. Not too easy, but not too hard. And so, there's not too much to talk about right now, despite the fact that I'm way over my word limit. Right now our major focus is to just have the riders be aware of what exactly is going on. To help them tune their own sense of feel. This focus will change as we hit more challenging stages.

Attached is Floyd's report. If you don't want to look at it, all you need to know is he did an average of 205 watts while moving, 250 while pedaling, spent 45 minutes coasting, burned 3075 Kjoules or 3167 Kcals, drank 10 bottles of water, lost only 0.4 kilograms of body weight, and thought the day was not easy, but not hard, but probably more easy than hard. I'm sure that makes perfect sense.

Powerfeed Stage 3: Developing A Sense Of Self

There's no context for any of the power values without a sense of what an athlete feels

By Allen Lim PhD

How'd you feel today? It's probably the most common question that the riders get asked when they roll in each day. How was it? All good? How'd it go? Cava?

Despite all of the technology we unleash on these guys and all the analysis we do each day, the bottom line is still feel. As a professional athlete at the Tour or a weekend warrior at a local triathlon, there is no substitute for developing a deep and intuitive sense of self. Not that these guys are ultra-sensitive touchy feely types, but when you ask them how they feel, they all have a pretty extensive vocabulary for it.

When I asked Victor Hugo Pena how he felt the other day, his first reaction was, "Oh ya, it was hard." Which was quickly qualified by an explanation that it was only hard because the race is just getting started this week and the legs are still "opening" up. That was further clarified by an explanation about how it wasn't actually hard relative to how hard it will get or can get or actually is or could be or should be. A couple of hand gestures and discussion points later, it all boiled down to, "So ya, it wasn't that hard. Maybe a 4, you know, compared to other races. But it was hot, so more like a 4.5." I was kind of spacing at this point, thinking about how this discussion might go for Victor "The Shark" Pena in the bedroom. That turned into a laugh and I replied, "Cool, she'll give you, I mean, we'll give you a 4.5."

We use a simple 1-10 rating of perceived exertion scale, popularized by Carl Foster, who demonstrated that taking a simple 1 to 10 measure of perceived intensity and multiplying it by time in minutes, gives an extraordinarily robust measure of an athlete's training load – a measure of load that could be used across different sports and which is predictive of changes in performance during the season. For me, this is probably one of the most important things we monitor each day. The bottom line is that there's no context for any of the power values without a sense of what an athlete feels. In fact, we're not using these numbers to tell these guys what to do. We're using these numbers so that they can develop a deeper understanding of their personal responses relative to an objective measure of their performance – its just feedback. And feedback is really the most important thing. Knowing that you need to hold a bazillion watts per kg for 30 minutes to win the Tour is one thing. Knowing that you feel great doing it. That's pretty cool.

Anyway, it's the Fourth of July and Floyd wants to blow something up, so I need to run and help celebrate. All is good with the team though Victor lost some time today. I haven't talked to him about it yet, but I'm sure the explanation will be good.

Powerfeed Stage 2: Just The Basics

All these power stats can be complex so we're breaking it down and giving you just the basics

By Allen Lim PhD

Now that we are two stages into the Tour and can actually start looking at averages (albeit only two days worth), I've included the basic data chart that we'll be giving you guys during the race. While I'll be adding other metrics here and there and focusing on different events over the course of the race, this chart will be the basic info that we'll compile each day. It's a lot less detailed than the report that we give the team and riders each night, but there's no way that I could get that much information across online each night, nor would the team be too happy about that. So here are the basics.

In the chart, you'll see a comparison of Floyd vs. the Team. Besides Floyd, the riders on the team who are being monitored include Victor Hugo Pena (The Shark), Nicolas Jalabert (The Poor Ja Ja), Koos Moerenhout (No nickname required), and Robbie Hunter (The Enforcer...for references, see Popovich vs. Hunter at the Tour of Georgia). For both Floyd and the Team, we'll be looking at what happened each day, the average for the Tour and the minimum as well as the maximum values.

Fundamentally, the most important feature is the average power while moving and while pedaling. At this point in time, the guys are trying to get as much "float" time as possible, so there's a fair amount of coasting which brings down the average power when moving while increasing the average power when pedaling.

The next set of data is the work information, which is simply the average power or intensity multiplied by time. I like to break the total work or load into what actually happened vs. what the riders actually felt happened. We're still trying to get our calibration and communication down for the team as a whole so until we nail that down I'm leaving the team info there as "not available."

On really hard days, you'll see big differentials between what happened and what the riders felt happened. Beyond average power and work, it's also important to look at how that power is distributed. For simplicity, I break that into three zones for the riders based on their perception of effort – easy to somewhat hard, somewhat hard to very hard, and anything over very hard. These three zones correlate almost perfectly to time below the lactate threshold, time at lactate threshold, and time above the lactate threshold. From a practical and linguistic standpoint, however, I find it's way easier to just use verbal cues for the zones. The high correlation means it works just the same for describing training distribution.

In the peak power category, the two time frames I find the riders most interested in are their 5-minute power and 30-minute power. The 5-minute power correlates highly with their power at maximal aerobic capacity (i.e., VO2 max), while the 30-minute power correlates highly with their lactate threshold power. Finally, the last feature, I've included is the number of times each rider attacks or surges above 10 watts per kilogram of body weight. Essentially, this is a top end anaerobic effort. It's a bullet and the more bullets a rider fires, the more fatigued they get regardless of the duration or average intensity. So it's a great way to look at how many punches get thrown each day. This is where Floyd suffered a lot last year. Our goal has been not to see that problem this year.

So there's the data for the day. As for other news, everything is pretty steady here at the Phonak camp. Having just left our first hotel, we're all just getting settled into a daily routine - working out the kinks and trying not to rip it to hard yet.

Powerfeed Stage 4: Keeping Floyd Cool

Subtle assistance by fellow teammates is critical to Floyd's success

By Allen Lim PhD

Today was a lot easier for the whole team. With a little bit of rain this morning, it wasn't as hot as it was yesterday and the terrain was less aggressive with only two categorized climbs as opposed to yesterday's five. As you can see from the summary data, the average power outputs were a lot lower. More importantly, there were fewer spikes in power. At any given power output, a steady profile is always easier than one that undulates a lot. With this in mind, the fact that Floyd cut the number of surges he did above 10 watts per kg of body weight by almost half played a key role in a more relaxed ride today.

While the terrain and the steady chase by Quick Step and Davitamon was a major factor contributing to this steadier profile, we noticed that in the previous days downloads that Robbie Hunter's power profiles were significantly steadier than any of his other teammates including Floyd. Floyd joked this morning that it was because no one screws with Robbie. So the suggestion was made that Floyd just follow Robbie. Looks like it helped.

It's this subtle assistance and the less subtle assistance of fetching water bottles or helping Floyd chase back on after a flat that will be critical to Floyd's success here at the Tour. In this first week, the only thing that the team is concerned about is making sure that Floyd has as easy as a ride as possible. In yesterday's race, for example, the guys estimate that they went back to the car close to 10 times for bottles. Most of those bottles ended up going to Floyd as he claims that he drank close to 20 over the stage. Based on the fact that he lost less than 300 grams of total water weight this might have been possible. In contrast, the rest of the team lost between 2 to 3 kilograms of water weight. It's like a bunch of worker bees flapping their wings to keep the queen cool. However it works. One thing is for sure: Floyd is staying pretty hydrated out there.

In the final sprint today, the team also did a fantastic job of bringing Floyd up to the front to keep him out of trouble. Robbie took a monster pull between the 5 km to go and 3 km to go markers and was the only one on the team to lose time. But it was worth it. We're just glad that the crash in the final didn't take Floyd out. Outside of that, it was another pretty uneventful day for us. The real news is that France won the football match tonight. The fireworks are definitely going off now. A day late perhaps, but this far away from home, we'll take what we can get.

Powerfeed Stage 5: An American Invasion

Team Phonak has done more than make American Floyd Landis their team leader--they've embraced his culture

By Allen Lim PhD

When we arrived to the hotel this afternoon we were greeted by the team mechanics in the parking lot. They were thrusting their arms high in the sky as we rolled in like they had just won something, screaming, "Thank You America, Thank You America." I just looked at them and smiled, thinking that they were just being goofballs or making fun of us. But when we got out of the car and we all said our hellos there was a real sincerity to their jocularity.

I had slept most of the way during the transfer and was still shaking off the grogginess as the mechanics met us and waved us over to the hotel restaurant for some food and drink. Cyrille, the lead mechanic here was in a super up-beat mood and immediately grabbed me to ask if I knew where we were, invading all of my personal space in the process. I was thinking that I was somewhere between his left armpit and nose, but I just looked at him and shook my head no. And as I shook, he looked me right in the eye and says, "You are in America." "What?" I ask. "AMERICA!" he enthusiastically replies.

Then it suddenly hit me that we were in the city of Caen, just below the D-Day invasion beaches. Utah, Omaha, Gold, Juno and Sword. As it dawned upon me, Cyrille begins expressing his thanks. In broken English and with a heavy French accent, he asks Jesse and I if we can imagine what it was like. He literally asks us why our country even cared. "If I am an American, I think, who is France. Why I die for this country." He motions like he's holding a machine gun and sounds, "ra-ta-tat-tat...ra-ta-tat-tat," then solemnly sighs, "O Mon Dieu." We get lunch and for the next hour, the staff assigned to work the hotel transfer, gathers around to talk. They ask about how my family immigrated to the U.S. I show them some pictures and they smile and laugh as I bring them back home. It was the first time I've heard one of the Spanish mechanics, Modesto, ever speak English, asking Cyrille how to say certain words so he could talk for himself.

For the most part, I've always felt like an outsider with this team. With the majority of my time spent with TIAA-CREF in the States, my agenda with this program has only been about helping Floyd. But as we sat their laughing and sharing, I realized that these guys were making me a part of their team. I also realized that more than any other team on the Pro Tour, this team - the management, staff, and sponsors, has done more than make an American their team leader. They've embraced his culture.

When I first met Cyrille in January he could barely speak a word of English. Since then English has become the official language of the team and in less than 6 months, he's practically fluent compared to my French. Last year, as I broke down Floyd's data at the races, I was essentially ignored. But in the fall they sent their team doc, Denise, to Boulder to learn more about what I did all year and now I spend my evenings writing reports for the staff and riders, meeting with Floyd and John Lelangué, the team's manager each morning to go over the numbers. In 2007, I-Shares, an American company will be taking over as the title sponsor and they've already shifted to other American products like Giro, Oakley, and Nike. At this year's Tour of California and Tour of Georgia the team sent their "A" squad to support Floyd, placing as much priority if not more on these races than many events here in Europe. Even in this year's Tour, the riders are completely committed to protecting Floyd. While he spent almost all of the first week at last year's Tour drifting solo towards the back, he's almost never out of the top 30 this year and is always surrounded by green and yellow. And finally, after introducing the team to keg sized cans of the caffeinated energy drink "Monster," at the Tour of California, Floyd has got the team addicted and we even have planned delivery dates for this sweet nectar here at the Tour.

Though it might be easy to call it another American invasion, compared to the sacrifices made here over sixty-two years ago, any comparison is moot. The metaphor that this race is a war...well compared to the history around us now, I'd say it's more like a water balloon fight. If there's any amount of importance in that or any social responsibility here, I guess it's that it makes people happy.

Today, Floyd barely avoided a handful of sketchy crashes and ended up having another relatively easy day on the bike. That makes us really happy. Attached below is a summary of the day's stats. Notice, that Floyd (today) and on average and the team (on average) threw a total of 31 water balloons thrown over 10 watts per kg by Floyd today (I checked the data...a weird quirk). But at some of the lowest average power outputs, they'll all be ready to fight tomorrow.

Powerfeed Stage 6: Looking Beyond the Surface

The numbers say the day was difficult, but American Floyd Landis felt otherwise

By Allen Lim PhD

If you just look at the numbers from today, you would think that this was the hardest stage of the Tour to date for Floyd. There were definitely new highs today - a 223-watt moving average (new max), a 275-watt average while pedaling (second highest by 1-watt), and a new maximum best 5-minute power output of 422 watts. But if you watched Floyd and the guys at dinner tonight, you would've thought that they just cruised around the park today. They were talkative, cracking jokes, and really relaxed. When I asked Floyd how the day felt, he commented that it was probably the easiest day so far. "Oh ya, it was easy," he remarked. "It was finally cool. It felt good, I could actually do some work."

Things are rarely what they appear on the surface and sometimes it's important to take a closer look. Today the real story was the weather giving the guys on the team some reprieve from what felt like oppressive heat on stage 3 and 4. It cooled down a lot yesterday as well which gave the guys an additional day to unwind before tomorrow's long time trial. In addition, the normally strong winds around Normandy we're relatively calm over the last two days and played no factor for us on either day of racing. While the riders did have a bit of a headwind in yesterday's stage, it was actually welcome.

As Floyd explains it, "It's always easier sitting in when there's a head wind. The speeds are lower and you get more draft." And he's right. Whenever he's sitting on and drafting into a head wind, his average power outputs are always lower compared to sitting in a tail wind. Today, there was slightly more cross and tail wind sections, and that was reflected by an increase in average power while moving from 196 watts yesterday to 218 watts today for the team. Similarly, Floyd's average from yesterday of 196 watts increased to 223 watts today. This same pattern was observed in the team and Floyd's power output while pedaling. And yet, from the rider's perspective today wasn't as difficult.

The initial heat stress experienced by the riders also resulted in what may initially appear to be surprising increases in body weights. For stage 1, 2, 3, and 4, the average body weights for the team were 71.47, 71.50, 71.49, and 71.58 kilograms before the start of each respective stage. These values aren't just pretty consistent, they're statistically insignificant differences. But on the morning of stage 4, every rider on the team showed an increase in body weight and the team average went up to 72.46 kilograms - an increase of 0.875 kilograms for the team. So what gives? Well, if we rate the heat index or load the riders faced on each stage, or even just look at the bottle count across the stages, we'd see that the heat load faced by the riders was normal, hot, way too hot, normal, cool, and almost cold for stage 1 through 6, respectively. That sudden increase in body weight occurred on stage 5, three days after the first really hot day at this year's Tour and after two continuous days of hot conditions.

Based on the timing, this increase is a normal part of heat acclimatization. While it may take a person who isn't use to exercising in the heat up to 2 weeks to adapt, elite athletes and individuals who have been previously exposed to exercise in hot weather can respond much more rapidly. For our population of riders, one of the first adaptations to the heat is an increase in plasma volume (i.e., an increase in plasma or fluid in blood) and drops in resting and exercising heart rates due to a net increase in the total cardiac output. This type of plasma volume expansion can range from 5 to 30%, and assuming a blood volume of 5 liters, may result in an increase in fluid weight of .25 to 1.5 kilograms. So we're in the ballpark. Normally, this expansion is also accompanied by an increase in salt retention and when the doctor checked the rider's electrolyte levels yesterday, there was a significant increase in sodium. And of course, because blood is composed of plasma and red blood cells, any increase in plasma would dilute red blood cell concentration. While this might scare many athletes, the fact of the matter is that it's not an athlete's hematocrit or concentration of red blood cells that matters, it's their total red blood cell mass. Keeping the same mass and increasing plasma which dilutes that mass actually improves performance as the output of the heart actually increases.

Ultimately, looking beyond the surface is often revealing. Power, weather, and an athlete's perception - these are all factors that play into performance. As we prepare for tomorrow's long time trial, reviewing and checking all of the elements of a fast ride is at forefront of all of our minds. So before I leave for the night, I'll leave you with one last thought. Amongst professional cyclists who are already so similar in their ability to produce power, it's unlikely that the strongest rider will win tomorrow's time trial. The winner will be one of the most aerodynamic. And with Floyd's seemingly "funny" position, we're feeling pretty good.

Powerfeed Stage 7: Everything Counts

Bad luck impacts Landis' time

By Allen Lim PhD

Back in early January, I was sitting in Floyd's garage as he was showing off his latest time trial innovations. He had recently sawed apart some black PVC pipe and hand bonded two sliced halves together to create armrests that literally cuffed his wrists together. They were zip tied near the top of his aero-bars as were a similar but wider (bigger pipe) set of pads closer to the bottom for his elbows. He was pretty excited about his latest creation. As he got on the bike to demonstrate the new position, I got pretty excited too. I imagine that if we worked some duck tape into the party we would've really impressed the ladies.

A month later, we reconvened at the Allied Aerospace wind tunnel in San Diego with a cast of characters that included Scott "the human wind tunnel" Warren, Mark Lucas a coach on scholarship from New Zealand, and members of the Phonak squad who brought a box full of goodies from BMC. After getting reference values for Floyd's 2005 position and equipment, we spent the next few days methodically testing part after part, body position after body position. We even broke out the clay, cardboard, and, of course, the duck tape. But the biggest revelation was Floyd's garage tinkered bars. After reconfirming the results and smiling as Floyd got his "I told you so" in with the team who never really felt his position was quite right, I thought to myself, "this guy knows speed."

Although it's initially difficult to see all of the changes made in Floyd's equipment and position from 2005 to 2006, the list of modifications is extensive. They include changes to his arm extensions, arm pads, handlebar fairing, water bottle, crank, stem, seat post, skewers, helmet, arm angle, arm width, seat position, and elbow placement. Each of these changes removed grams of drag -- in some instances 15 to 20 grams and in other instances just over a 100. While this might seem a bit obsessive, even minute changes in aerodynamic drag can result in enormous changes in power.

Specifically, aerodynamic drag changes exponentially with speed, while the power to overcome aerodynamic drag changes cubically with speed. That means if you want to double your speed on a flat road, you need to increase your power eight-fold. Another way to think about it is to realize that at 30 mph an average professional cyclist may only have about 2600 grams or 2.6 kilograms of drag holding them back. You could literally lasso a cyclist galloping along at 30 mph and pull back with a force equivalent to dropping a 6-pound weight and stop them in their tracks. Most kids can curl more than that. Moreover, relative to the weight bike manufacturers attempt to shave off their frames to help overcome gravitational resistance, the amount of speed gained going uphill by dropping a pound of weight off your bike is negligible compared to a pound of drag on the flats.

In today's time trial, some bad luck and the subsequent addition of some extra grams of drag may not have lost him the race, but these events definitely had an impact on his final time. Before the start, we modeled that in the worst-case scenario, Floyd would finish with a time of 1 hour, 2 minutes, and 6 seconds. In the best-case scenario he would finish in a time of 1 hour, 1 minute, and 35 seconds. This 31-second spread amounts to a power range of only 10-watts. In reality, Floyd came in at 1 hour, 2 minutes, and 44 seconds for 2nd place - a whole 38 seconds off our worst-case scenario, 70 seconds off of what we hoped, and 60 seconds off the winning time. So what happened?

Well, the first thing that happened was Floyd had a bit of a mishap. At kilometer 13 he hit a speed bump and this bar extensions snapped clean off. It was amazing he didn't crash. So Floyd gets a bike change, losing valuable time, and switches to a spare bike that is missing the new prototype water bottle that was on his first. Then, and I can't even believe this happened, but his bars on the second bike slipped forward. After reviewing some of our wind tunnel data, I estimate that the loss of the bottle and the change in handlebar position, gave Floyd 80-grams of additional drag. At his velocity and assuming the length of 52 kilometers this is equivalent to an additional 38-seconds. So had Floyd been on his original bicycle, he would only be about 23-seconds out of first place. And that 23-seconds could've easily been lost in the bike change. On T.V., it looked like the time lost was about 20 seconds. Assuming a 20 second bike change and 80-grams of extra drag, Floyd still might have lost by about 3 seconds or a 1/4 to 1/2 of a watt. In any case, that's bike racing. Everything counts but in the end, it is what it is. Things should've, could've and would've been better if this and if that. But who really knows. We're all just glad that he's safe and still had a great ride despite a few problems. He kept it cool today and based on his "virtual" power that I've modeled between 410 to 417 watts he's on track for a great Tour.

| | Time | | | Power |
|--|------|-----|-----|-------|
| | Hrs | Min | Sec | |
| Floyd's actual time plus 80 grams of extra drag: | 1 | 2 | 44 | 410 |
| Floyd's actual time with a 20 sec bike change and 80 grams of extra drag: | 1 | 2 | 44 | 417 |
| Floyd's Virtual Time without 80 extra grams of drag: | 1 | 2 | 6 | 410 |
| Floyd's virtual time without a 20 second bike change and without 80 extra grams of drag: | 1 | 1 | 46 | 417 |

Powerfeed Stage 8: Bridging The Gap

The gap between the next generation of American cyclists and Floyd boils down to time and hard work.

By Allen Lim PhD

Note:

Because of the rest day tomorrow and the transfer down to Bordeaux, the bicycles won't be arriving until late tonight and the riders won't be here until tomorrow. As a result, I'll be posting the power data from Floyd and the team for today's stage tomorrow after I catch up with them. From what I've been told, the team had to do some work today to keep the breakaway in check, but neither the team nor Floyd were all that stressed.

Since we weren't going to get the computers this evening I thought I'd review some data from Floyd's Tour of Georgia to write about. But that got me thinking about other things, so on the car drive down, I wrote the following story. And yes, I am really carsick now.

Bridging the Gap:

It had been a long day in the car and I was anxious to get back to the hotel. I was following Mike Friedman, Brad Huff, Rahsaan Bahati, and Mike Creed - members of Team TIAA-CREF and some of America's most talented up and coming cyclists - on a training ride in the Pinos Altos National Park just outside of Silver City New Mexico. It was the first week of February and most of us had already been on the road for the past two months. Road weary does not even come close to describing how we all felt. The 5 hours in the car that day felt like an eternity and I was beat. But it was a small thing compared to the weariness I could see in the boys. We still had 45 minutes to go, but every mile the speed steadily waned. So when I saw Rahsaan pull off the road exhausted, my first instinct was to just pack him up in the car. His day was over. Or so it appeared.

As I pulled over to talk to Rahsaan, his head hung low over his handlebars and he straddled his bike like a rag doll. I got out of the car and walked over but he didn't look like he wanted to talk to anyone. I approached slowly to give him some time and to figure out what I was going to say. But before I reached him, Mike Creed who had been slaughtering the guys all day rolled over and crouched down so that his head was even with Rahsaan's.

Angry, surly, and intense are just a few adjectives to describe Creed and I felt a twinge of apprehension as I prepared to listen to what he was about to levy on Rahsaan. But the words that came out of Creed's mouth weren't mean or aggressive. They were gentle and calm. "I know it hurts man. I know you want to stop," he said, "but this is the only way. This is the only way." Before I could say anything, Rahsaan took a deep breath, clipped back into his pedals and got back on the road. And as I got back in the car to follow, those simple words kept echoing in my head. "This is the only way...this is the only way."

What will it take to bring the next generation of American's to the Tour and are we even capable? As I sit here in France watching Floyd take on the World, my mind keeps drifting back to that day outside of Silver City and the enormity of what lies ahead for those young men. But what I've come to realize, what I believe, is that the U.S. is home to some of the most talented cyclists in the world - that when it comes to raw power, we could fill the peleton here at the Tour with a pretty sizable cottage of wattage. But power and talent don't always mean results and at the end of the day there is no prize for best 5-minute power.

This point hit home this morning when I was reviewing Floyd's power data from the Brasstown Bald stage at this year's Tour of Georgia and decided to compare his numbers and results with the power data I gathered from TIAA-CREF rider Will Frishkorn. On this particular day, Floyd redeemed himself with an amazing ride up Brasstown Bald, holding onto the wheel of climbing phenom Tom Danielson to ensure his overall win at Georgia a year after losing to Tom by seconds. Seventy some odd riders and over 18 minutes later, Will rolled across the line. That's not just a small gap, that's a whole other race.

But when you look at the numbers for Floyd and Will you wouldn't be able to predict the chasm in the results. As an example, Will finished with a higher average power output while moving and while pedaling, did more work, spent more time between 4 to 6 watts per kg and above 6 watts per kg, and had a higher peak power output for 5-minutes than Floyd. In addition, he was about a kilogram lighter than Floyd at the time, which significantly raises his power to weight ratio.

So what happened? Well basically, Will had an incredible ride, but his goals that day were different from Floyd's. Will's job was to help Lucas Euser, our team's KOM leader into an early breakaway. Not only did Will do this, he drove the break taking two pulls for each pull taken by the 4 other breakaway companions with Lucas sitting on. After helping Lucas make it to the KOM climbs so he could duke it out with Jason McCartney, he throttled back and rode in easy over Unicoi Gap and Brasstown Bald. As a side note, we saw the same higher power values in the Phonak riders who spent all day working to support Floyd.

The fact that race tactics plays such an important role in both an athlete's power profile as well as the end result is one of the reason's why Floyd is so open about sharing his power information. Beyond tactics, terrain, weather, food intake, and mindset are also critical determinants of performance. Thus, you can't assume you know anything about the rider or the race by just looking at the numbers. As a result, Floyd knows he's really not giving anything away unless there's another Floyd Landis in the peleton doing the same ride and having the same experiences. At the end of the day, he is the only one who understands the myriad of factors that impact his race.

With that in mind, the numbers are extremely telling if you don't ignore and stay aware of how these factors impact you. In fact, having the power data is the best tool we have in parsing out all of these complex variables. It helps us to understand if the differences we see between riders are actually physiologic or psychological, technical or cultural, giving us references that are critical to goal setting.

So if we discover a cyclist who is only a 1/2 watt per kg away from being capable of winning the Tour, we can set goals to help that athlete develop. But it's not just, hey you need to do an extra 1/2 watt per kg, it's you need to do an extra 1/2 watt per kg when you don't want to be at the races, when it's cold and miserable, when you're missing your girlfriend, don't speak the language, are missing your bags, and feel terrible. Because the bottom line as a pro is it's your job now. And sometimes, going to work sucks. In the end the gap between the next generation of American cyclists and Floyd boils down to time and hard work. It's been and will continue to be the only way.

Three months after Rahsaan had his rear handed to him on that training ride outside of Silver City, he returned for the Gila Stage race. On one of the stages the team rode brilliantly to bring back a breakaway and lead him out for the sprint, but he didn't come through for the guys. The next day, however, in the criterium he made us all proud when he lit up the sprint for an impressive win. It was the first time an African American has ever won a race on the US National Racing Calendar. Perhaps in a few years down the Champs Elysees, history will be made again.

| Unicoi Gap | | | | | | |
|------------|------|------|-----|-------|------|---------|
| | Min | Sec | Km | Power | W/Kg | Cadence |
| Floyd | 13.0 | 38.0 | 5.5 | 376.0 | 5.4 | 90.0 |
| Will | 16.0 | 58.0 | 5.5 | 318.0 | 4.6 | 77.0 |

| Brasstown | | | | | | |

Powerfeed Stage 9: Floyd's Avascular Necrosis

Floyd is human, he's vulnerable, and he feels pain - everyday

By Allen Lim PhD

I wasn't quite sure how to approach today's story, so I went and asked Floyd what he thought I should say. His response was simple. "Just talk about it from your perspective," he told me.

My perspective? I can't even begin to imagine that my perspective can do the situation justice. And I guess from my perspective we've kept it a secret for so long that I don't even know how to talk about it without wanting to hide from people the misery I've seen him go through. Because it means he's human, he's vulnerable, and he feels pain - everyday.

I found out that Floyd had avascular necrosis the very first day I met him. We were supposed to be talking about his upcoming camp, but after a little bit of small talk, he just started pebbling me with questions. "What do you know about avascular necrosis?" "Do you think I can ride with an artificial hip?" "How long do you think I can go before I need to get it a new one?" I was completely unprepared.

About a month later, Floyd had surgery to try and increase the blood flow to his right hip. A hip that from every x-ray and MRI I saw was just thrashed. Bone on bone - an oddly shaped and atrophied shaft that fit into the socket like a square peg rammed into a circle. He didn't tell me about the surgery until after he had it done and when I asked if he told the team, he told me no. I understood. It had been a rough enough transition from the U.S. Postal Cycling Team to Phonak and he was afraid he'd lose his job. So from that point on, we stopped talking about his hip. Instead it was his finger.

I could always see the misery in his face when it hurt. Simple things like walking, getting out of a chair, and straddling his bike before a ride were difficult. If you didn't know him, you'd mistake the look for anger or a sarcastic scowl. His training and racing were at times erratic and he generally opted to ride alone so that he could hide his obvious discomfort from others. Sadly, I often felt that the energy it took to hide it wore on him more than the grinding mass inside him.

When we talked tonight he was the most relaxed I think I've ever seen him. It was as if telling the world had lifted an enormous weight. We joked that it was one less thing he had to worry about now, and one more thing for everyone else to think about. That he was giving everyone the "finger." But then he asked, "Do you think I'll be here next year?" I said, "You'll be here next year." He paused and whispered, "I'm scared." I had no reply.

All I know is that he needed to tell people what was really going on and that he couldn't wait. He had to free himself of the burden before tomorrow's stage when the Tour really begins. He didn't want to make excuses, but he was sick of people assuming that they knew what was really going on.

I asked him, "Do you remember the tunnel." He laughed and said, "Ha! They must of thought I was a real jerk." I rolled my eyes and said, "Ya you were a real ass." We went to the tunnel because we needed to find a position that wasn't just more aerodynamic, but one he could pedal in. He built those bars because it was the only way he could open up his hip angle. But nobody else knew that. And when they suggested a different position, one that appeared even faster than his position now, he just walked out and curtly told everyone, "I'm done."

I sat there not saying a word as the others shook their heads in dismay and disgust. I sat there and thought about the first week of last year's Tour. About how he'd sometimes come into the bus after a stage and tell me how he thought he was going to vomit, the pain was so bad. But it never stopped him.

We all have fears. After all, the world is an uncertain place. But when you accept it, when you bathe in it for a long enough time, the surprising thing is that it becomes all right. You can't hide from it cause it'll find you. As long as you keep on moving forward...as long as you don't give up there will always be enough hope to balance the doubt. So we're going to keep moving forward. One day at a time. Cause as Floyd puts it, "I'm 100% of what I am now." And he's right. That's just who he is - one hundred percent all the time. Kind of puts all the data in a different perspective doesn't it.

Powerfeed Stage 10: The Mountains

It's nice to get this show going and boy is it going

By Allen Lim PhD

We are finally in the mountains. It's nice to get this show going and boy is it going. Today, Floyd hit new maximums for average power, total work, time spent at and above his lactate threshold, peak power for 5 minutes, and peak power for 30 minutes. And yet, the day still wasn't quite as hard as it could have been.

The first major climb today was the Col d'Osquich. It started 44 km into the race and took 14 minutes for an average power output of 344 watts. That wattage is actually lower than the average 10 minute best that Floyd has already accumulated through this race, so it was pretty light. The next climb of the day was the Col de Soudet, 87 km into the race. That took the front group 44 minutes to climb and Floyd averaged 355 watts up it. Again, well within limits. And finally, the Col de Marie Blanche, 141 km into the race took the main peloton 28 minutes for an average of 366 watts for Floyd.

Still, many riders including some from our squad did have some difficulty. The transition from riding the flats to the climbs can be pretty rough so the team's staying pretty relaxed about the situation. Part of the difficulty probably stemmed from the fact that there were a lot more riders around fighting for position at the base of those three climbs. In Floyd's power profile, the surges leading up to those climbs were frequent and volatile. Though, he didn't surge much above 10 watts per kg he had almost 500 spikes above 6 watts per kg. Although those surges only last for 1 to 10 seconds on average, there enough to tenderize even the toughest rider after a while.

Otherwise, there really aren't too many dramatic stories to tell about the day. I bumped into Dave Zabriskie and he sang for me at the start, Tom Boonen showed me all of the different World Championship decals on his bicycle, Christian VandeVelde waxed philosophic about a big chocolate croissant he had for breakfast, and Floyd recited a bunch of Jack Handy quotes. One about seeing someone fall on an ant and not laughing cause you could've been that ant was particularly funny. Finally, when I got to the hotel today, the staff and I had a really good time watching the race on T.V. At fist we were all screaming and yelling, but after about an hour all 5 of us fell asleep. That was a good nap. So that's about it for today. The race has begun. Tomorrow won't be as easy. But I think I'll still take a nap.

Powerfeed Stage 11: The Pride Of Floyd Landis

Realizing a dream not only requires phenomenal personal effort, it requires the acceptance of a phenomenal group effort

By Allen Lim PhD

When I watched Floyd cross the line today, I had to take a moment and step out for some air. So I got on my bike and rode up the mountain away from the team hotel. About a mile down the road I got a call from Robbie Ventura who was at the finish. Robbie could barely talk he was so choked up, which got me all choked up. He told me that when he saw Floyd, the look in his eyes...well, the look was something he had never seen before. The man was so proud.

At dinner tonight, we all lifted our glasses for the man, for Floyd. He was initially coy, perhaps surprised or uncomfortable with all of the attention. But then his eyes smiled brightly and I saw what Robbie was talking about – a lifetime of effort accumulating in a singular moment of self-respect. And as we celebrated I marveled at how present everyone was to this moment. As if time had just stopped.

It struck me in that moment, that realizing our dreams not only requires phenomenal personal effort, it requires the acceptance of a phenomenal group effort. I realized that Floyd's initial shyness at accepting the congratulations of so many was the same hesitation that any of us have when we ask anything of anyone.

We live in a culture where we're taught that asking is a sign of weakness. That being self-reliant, pulling harder on one's bootstraps, and going it alone is the only way to prove our worth. But so many people have come together to help see this moment happen. To see this yellow gown bestowed upon our leader. So many people share in this dream, simply because he asked.

There names are, Bert Grabsch, Robbie Hunter, Nicolas Jalabert, Axel Merckx, Koos Moerenhout, Alex Moos, Victor Hugo Pena, Miguel Angel Perdiguero, Andy Rihs, John Lelangue, Juan Fernandez, Jacques Michaud, Adriano Baffi, Monika Zuercher, Georges Luechinger, Denise Demir, Markus Sugg, Jose Luis Boente, Moises Leboso, Moises Leboso Jr., Juan Pujol, Jose Teixeira, Freddy Viaene, Werner Lenk, Modesto Perez, Cyrille Perrin, Antonio Rodriguez, and Gisbert Kunz. They all raised their glasses tonight. These are the names that make up the team here in France, brought together to support one man, who's here to support this entire family. And right now, we are all so proud.

Below is a summary of today's data. Again, Floyd has achieved new maximum values in almost every metric we measure. Compared to last year, however, Floyd has still not yet hit the same peaks. Of course, he also played a tactically conservative race, following wheels, and waiting for the simple attrition of the climbs to wear people out. There wasn't a single climb that was exceptionally difficult. In fact, the climbing speeds or V.A.M rates (vertical ascent in meters per hour) are significantly lower this year compared to last. But the simple number and duration of climbs took its toll and while everyone will be tired tomorrow, some of the hardest racing is still to come.

Powerfeed Stage 12: Tough Day

Despite the lack of climbs, the pace and heat took its toll

By Allen Lim PhD

Despite not having any major climbs longer than 15 minutes today, the speed and the heat definitely made things difficult. At an average power output of 244 watts and just under 4,100 kcals burned, the overall intensity and load today was only slightly less than the first day in the Pyrenees (stage 10). Unlike that first day, however, the variability in power and overall speeds were significantly higher today.

When the power profile is less steady, the strain on the body is much greater. It's similar to the way that stop and go traffic with continuously high revs is hard on your car and bad for gas mileage. But unlike stop and go traffic, the speeds today were extremely fast. So imagine jerking back and forth in a car as the driver continuously accelerates and decelerates all above the going highway speed limit. In a crude way, that's what it probably felt like for Floyd today.

Now imagine doing that in a convertible on an extremely clear, hot, and sunny day. Not that I laughed, but when I saw Floyd come to dinner tonight he had this boiled lobster like glow to him. Perhaps all that yellow he had on today was reflecting more rays.

Another contributing factor to the hard day was some very aggressive riding by other teams that put Phonak on the offensive. Many of the attacks were short and volatile and so it's not so surprising that Floyd hit new maximum values for his best 5-minute and 10-minute power output at 465 and 426 watts, respectively. While they are the highest we've seen in this year's Tour, they're still lower than the best 5-minute of 478 watts and 435 watts we observed last year. So just like yesterday, the stages are getting harder, but the most difficult days are still likely to come.

One last note, in the final 2 kilometers, Floyd threw 7 surges over 10 watts per kilogram of body weight. For Floyd, that type of an effort is a full on sprint. And it's not like Floyd is exactly known for his sprinting abilities. I've actually never seen him put those many top end efforts in the final kilometers of a stage. I think Floyd was equally surprised. The expression on his face when he asked, "did you see that finish man," was the same kind of expression someone has when they asked if you saw the road kill down the road. Still, the fact that Floyd had the motivation and energy to follow the sprinters at the end as they duked it out is a really good sign. Other than that, all is good at the Phonak camp. And that yellow bike. Ya, it's pretty cool.

Powerfeed Stage 13: Hot

The guys were slower, thirstier and more miserable thanks to the warm temps that filled the day

By Allen Lim PhD

In my expert opinion it was hot - really, really, really hot. A Claustrophobic, oppressive, and unkind hot. The kind of hot that makes you want to curl up under whatever patch of shade you can find and suck on a Popsicle. Except you don't have a Popsicle and if you did it would just melt all over you before you could even lick it. And then you'd just be one hot sticky mess. That's how the guys felt and looked when they came across the line today. Of course, my training makes me an expert at recognizing frustrated melted Popsicle heat syndrome.

We could quantify the physiological effect of this type of heat in many ways since heat, like power, is just another form of energy. I was actually planning on transmitting our GPS data to a geographical information system network so we could get real time information about the wind, humidity, temperature, and radiation on the course. My intent was to overlay this data with Floyd's power profile to produce a second to second animated thermograph. Since we know his gross mechanical efficiency, his body surface area, and the heat of vaporization of sweat (0.56 kcals per ml evaporated) it would have been easy to calculate the net thermal heat exchange via conduction, convection, radiation, and evaporation given all the other known variables. But, only after quantifying his total fluid consumption and body mass change over the race. Unfortunately, Floyd didn't want to step on the scale today, I think after someone made a comment about how well the I-Shares logo stood out on his shorts. So I got screwed on that project. But I guess the lesson is, if anyone ever asks you if his or her butt logo makes him or her look fat, in the name of science, just say no!

So to answer the question that's probably on everyone's mind; that question, of course, being, what kind of impact did the heat play on the riders today, I'll just have to assume that the following was due to the heat. First, they were all a lot slower (slowest flat stage so far). Second, they had to drink a ton (at least 20 bottles for Floyd from what he recalls). And third, they were miserable, which is of course relative. After all, the podium girls are hot everyday and when you realize that, you just don't feel as bad.

Actually, today was really unique as the average power was the lowest it's been all Tour at a measly or perhaps toasty 178 watts. Actually, today's average power was only 14 watts higher than the ride into Paris last year. And that day, those guys were drinking champagne, not Gatorade. In any case, the time spent between zero watts to a somewhat hard intensity was the greatest it's been all Tour while the time spent above a very hard intensity was the least it's been for the Tour. Finally, the power profile was also the steadiest it's been all Tour. What all of this tells us is that the guys were crawling today. And with the limited data I have, once again, I can only assume that this was due to the heat, which at one point caused the thermometer in the car to read 42 degrees Celsius or 108 °F.

Tactically, the guys weren't going to do diddly about the breakaway. It's like the movie, "The Sandlot," where its just way too hot to play baseball and the guys go to the pool and in a moment of true genius, Michael "Squints" Palledorous puts the move on Wendy the lifeguard. Except that, the guys couldn't go swimming today. And I'm not exactly sure if anyone kissed Wendy. Instead, they actually eased up near the end to give Oscar P the jersey - a friendly game of hot potato. It's a good move. There's no reason we need to burn anything before the Alps.

Below is a summary of today's data. And since you probably can't read it, you'll just have to trust me. Floyd moved slowly and it was hot.

Powerfeed Stage 14: The Daily Grind

The daily routine is well...so routine I don't even know where we are anymore.

By Allen Lim PhD

As exciting as it is to be part of the Tour, there's very little glamour about the daily grind. This morning at breakfast, it was obvious that the long days are beginning to wear on both the riders and staff. It was quieter and everyone looked a bit tired. Not the "I can't go on" tired, but more like the, "I wish I could take a nap...and maybe even suck my thumb...with a pillow between my knees." You know, that kind of tired.

Each morning the staff typically wakes up at 6:30 to 7:00 am, for breakfast at 7 or 7:30. Gisbert, our chef is usually up a little earlier getting the race muesli (a mix of organic oats, yogurt, nuts, dried fruit, fresh fruit, preserve, honey, & cream), assorted cereals (ranging from Special K to Sugar Smacks), pasta, rice, sauce, cheese, omelets, yogurt, coffee, tea, milk, soy milk, juice, chocolate croissants, apple strudels, fresh fruit, and assorted vitamins and supplements. Of course, most of this food is for the riders. For the staff the norm is some coffee, a croissant, and maybe a little muesli.

In any case, breakfast normally lasts about 30-minutes and then the mechanics and soigneurs are out getting everything ready for the day. Tires are pumped and bikes are inspected. Cars are washed, vacuumed, and racked with spare bikes (Floyd has two on each of the two follow cars). The van is racked with race bikes (Floyd's race bike is identified with a red saddle). The bus is disinfected (how this is done I have no idea). Vehicles are fueled. Two hundred and fifty to three hundred bottles with a carbohydrate and electrolyte solution are filled. Coolers are packed with these bottles as well as water, Coke, Red Bull, and Orangina. Bottles of frozen water are hammered apart for ice. Sandwiches for staff (lunch) and riders (post-race) are prepared. Race food ranging from fresh fruit, to little sandwiches, pastries, energy bars, and candy bars are wrapped in a special paper foil that makes it easier for the riders to open. Thirty musette bags filled with two bottles, two gels, two bars, two candy bars, two pastries, and some fruit are made. Luggage is brought down and packed in the truck. Clean laundry is sorted and distributed. Rain bags (individual bags filled with each rider's rain cape, spare shoes, change of race clothes, gloves, and extra helmet) are inspected and loaded. Food is loaded in the camper. Finally, race coordinates and deviations are programmed in each vehicle's GPS.

Once all of this is done, the mechanics truck, camper with food, and one soigneur van head to next hotel at about 10 am to unload bags, prepare kitchen, and organize rooms. Two caravan cars, one media car, the bus, and a soigneur van sit waiting to take the riders to the race at around 10:30 am.

The riders are typically scheduled to wake up an hour later and usually trickle in at about 8 or 8:30 for breakfast. The exception is Floyd who every morning of the Tour has been up with the staff and is normally at breakfast with them. The funny thing is that we have separate tables set up for staff and riders since our staff is so large and because the rider's table has so much more food on it. It's kind of like the adult table and the kid's table at Thanksgiving. So Floyd always ends up eating breakfast alone at this smaller table filled with way too much food, while 20 staff members all sit at a separate even larger table staring at him. I always give him a nod and he just looks around and shrugs his shoulders. After Floyd eats, he goes back to sleep and usually waits until the last minute to get on the bus in normal street clothes while the other riders all suit up before. Floyd's not big on chamois time.

The riders usually get to the race an hour before the start and have a meeting with the team's directors in the bus about the day's tactics. Then they hang out in the bus and smack talk behind the very darkly tinted windows. Sometimes, I leave them things to ponder, like web print outs of articles from "The Onion," Jack Handy quotes, and pictures of various types of American and European mullets. I'm sure this kills lots of time. Or they just get a coffee in the Tour Village. You can also get a hair cut and samples of local cuisine in the Village. I plan to get my head completely shaved there while eating a crepe before the final time trial. Somewhere in this time the riders also sign in and about 10 minutes before the start roll to the line. The race starts and grown men suffer for the next 4 to 6 hours.

Back at the next team hotel, we're hauling staff and rider bags into each of their respective rooms after just finishing a 2 to 3 hour drive in gridlock. The unloading and distribution of bags is equally time consuming and involves a lot of sweating and grunting. Except nobody's naked. It really sucks. While the bags are getting done, Gisbert or "Chef Man" as I call him (he calls me "Computer Man"), goes shopping for fresh organic food and prepares the kitchen. He tells me that the most important part of his job is making sure the kitchens are sanitary as food poisoning at the Tour isn't just something Floyd makes fun of, it's actually a very real possibility. At the same time, the mechanics are busy getting their work area together and catching up on anything mechanical they have to do. After the bags are done, I start number crunching and preparing my daily stories while watching the Tour on T.V. If the soigneurs and mechanics are done with their work, we usually all gather in the lobby or one room to watch the race. Almost always, everyone falls asleep while watching.

When the riders get done with the race, they either ride back to the hotel (as happened today) or they shower in the bus, refuel, and settle in for a 30 minute to 2 hour transfer to the hotel depending on where we are staying relative to the finish. The guys head directly to the "Food Room" where more muesli, fresh fruit, sandwiches, cereal, fluid, and all sorts of Scooby snacks are waiting. They then get checked on by the team docs, get a massage, then get any adjustments or rehab work done by our osteopath.

By 8:30 pm the riders are having dinner that starts with pasta, rice, potatoes, or all of the above with eggs, sauce, and fresh Parmesan cheese. Then they have a big salad. Once their done with this, they actually have a normal dinner -- the same dinner that the staff will eventually have about an hour later. Desert is always a possibility as is wine and lots of cheese. We are, after all, in France.

I normally skip dinner to crunch the data from the day and to write these stories. Eventually, everyone goes to bed and we repeat. Nothing changes. I don't even know where we are anymore.

With that in mind, today was another hard day. Go figure. Actually, it was really unique because the stats were very comparable to stage 11 -- the hardest stage so far. Floyd held an average of 265 watts today, only 3 watts less than stage 11. The difference was that today's stage was shorter and over flatter terrain. So the riding was less steady and extremely volatile, especially in the first hour. In fact, today Floyd did more surges above 8 and 10 watts per kg of body weight than any day of the Tour. Those accelerations aren't his forte, so today was a tough one. The nice thing is that Floyd likes it hard, because if it's hard for him, it means everyone is hurting. That all said, tomorrows rest day is really welcome - for all of us.

Powerfeed Stage 15: All That Matters is Yellow

Confidence and happiness abound in the Phonak camp

By Allen Lim PhD

Today was a beautiful day. It's hard to describe the emotion here at the Phonak camp so I won't even try. I'll just say that Floyd is happy and confident. We all are.

On the course today he was strong, in control, and had a tactically and physically perfect race. More importantly, the team showed its strength today and proved that they can be there for Floyd when it counts the most. Perdiguer's lead out at the base of L'Alpe d'Huez was perfect. Merckx, making the early break and then his strong work in the final, could not have worked out any better for Floyd. In the end, it was all up to Kloden to do the work as he was down on GC from Floyd and had to fight to try to separate himself from Floyd and the others. But Floyd was simply too strong to be dropped and though he could have gone on the attack, right now, yellow is the only thing that matters.

With that in mind, we had some unfortunate luck with the PowerTap. Floyd got a flat 100km into the race and because of the wheel change we lost data from that point on. So we missed some of the most critical data of the Tour, it's a real bummer. We dropped the keys in molten lava...again. But, yellow is the only thing that matters.

In an attempt to salvage or resurrect some data, I went and talked to Michael Georges of Matsport, the man responsible for timing this entire race. He took me on a tour earlier today and showed me how all the timing systems work- the chips on the bicycles, the timing sensors on the road, and the GPS network that gives them real time info on time gaps. It was computer geek nirvana, not that I was impressed or anything. Anyway, he told me that he had set up some special sensors at the base of L'Alpe d'Huez today so that he could get everyone's time up the mountain. It was just something he was interested in. So I tracked him down and he has offered to give me all the splits. The terrain profile on L'Alpe d'Huez is so detailed that it will be possible to get a fairly accurate estimate of Floyd's power on the climb. It will take me some extra time tonight to crunch those numbers, but hopefully I'll be able to report a bit on that tomorrow.

As for tomorrow, my thought is that it will be one of the most important days of the Tour. Yes, today was hard, but we know from the Dauphine earlier this year that the 18.4 km climb up to Toussuire, though not the steepest, will take it's toll, especially after the Galibier (42.8 km, 4.5%), Col de-La-Croix de Fer (22.7km, 6.9%), and Col du Mollard (5.8km, 6.8%). So it's still one day at a time. It's just how dreams work. One day at a time. And right now the dream is yellow.

Powerfeed Stage 16: Perspective

Despite cracking on today's stage, the fire is still there and Floyd isn't going home without a proper fight

By Allen Lim PhD

What do you say after a day like today? Do you say that it's all right when it's actually not? Do you sit around and micro-analyze every detail to find an answer when you'll never really know? Or do you just say it is what it was - a really bad day.

After the chaos of media and spectators died down tonight a few of us stepped out with Floyd for a beer. Rather than being in a fowl mood, Floyd was just happy to be acting like a normal person again. As we sat there, he got a text message from Jonathan Vaughters that got him laughing as he announced, "this is the best thing I've heard all day." Floyd read the message to us. A message that basically said, "I know that everyone is telling you that it's all okay and to keep it in perspective, that it's not the end of the world. But this sucks ass!" Finally, a little bit of truth...today sucked ass.

Everybody is doing the best they can otherwise they'd be doing better. That was one of my lines for the evening. Floyd's response was something on the order of, "What kind of crack are you on?" I replied, "Well at least we'll have something to do for next year." His answer was short and sweet, "I'm going to kick your ass." So I'm happy to report that despite cracking on today's stage, the fire is still there and this boy isn't going home without a proper fight.

Long story short, he didn't feel good from the get go. Yesterday was a big effort and no matter what you do, sometimes a big effort means the next day isn't going to be so pretty. There's no amount of eating, sleep, magic potion mixing, or aromatherapy that is going to fix that in under 18 hours, especially after 2 weeks of racing. Floyd didn't bonk, he wasn't dehydrated, and his hip didn't feel bad. It just wasn't there for him. He felt awful and spent most of the day in damage control.

For every rider at the Tour, bad days just happen. In the end, which day your number gets called is almost luck of the draw. If today's terrain had been even a notch lighter, he would've been all right. Why did it have to be today? I don't know. But not everything is due to random chance or lives in the realm of mystery. We're better than that and hopefully in time smarter than that. All we know now, is the Tour is unrelenting. It's like no other test of human strength and determination and at times it's just simply unreasonable, not just for Floyd but also for everyone who suffered up to Toussuire today. We'll figure it out though. He'll figure it out.

In time, he'll understand why an otherwise reasonable average power output of 259 watts felt like he was being beat by a wrecking ball. The previous and current days nutritional, energy, and fluid intake will be re-assessed. Files will be compared and analyzed. The latest scientific journals will be dissected. Ideas will come and plans will be made, tested, and re-tested. And sometime next week Floyd will be back at home drinking a beer in his yard with a big old smile on his face. So rather than analyze his power profile and GPS data from today, I'm just going to enjoy thinking about next week and the possibilities that still remain between. Cause this race isn't over yet. He's just angrier now and the dream remains - raw, unsympathetic, and once again provoked.

Yes, today sucked. And yes, maybe it doesn't help to try and keep it in perspective. But, I am beaming with pride for Floyd tonight. Because, without even knowing it, he's got it in perspective - he's made it all okay. He's wiped off the dirt and is getting on with it. I mean we all know that the world loves a winner, but at the end of the day, hopefully your friends, your family, well, hopefully, they only love you. That's Power.

Bicycling

Powerfeed Stage 17: Redemption

Today Floyd proved that he has it. Today he gave everyone a reason to believe.

By Allen Lim PhD

I'm so overwhelmed right now, I can barely even write. This morning he was so angry...so mad at himself. He had the music cranked to max as he paced around his tiny hotel room like a wild animal, foraging for his belongings so he could pack his suitcase for the transfer. His appetite for redemption was so raw and you could see his thirst for blood as he proclaimed, "I'm the strongest guy in this race! And yesterday was crap! I may lose this Tour, but it's going to cost them!"

I stood there with a scale and a piece of paper in my hand. "I need to weigh you," I said. His attention suddenly shifted and with one quick shove he slammed the bed up against the wall to open up some floor space. "Here, we've got some room now and you can sit on the bed," he said. I put the scale on the floor and he threw me a small book. It was a book of Jack Handy quotes that I asked Scott Thompson from Quality Bicycle Products to send. "Scott sent these," he said proudly. "I know," I said. And then we just sat there and read each other Jack Handy quotes for the next 15-minutes. He laughed louder than I think I've heard him laugh all Tour.

I showed him the piece of paper. On one side was every reason I could think of for his bad day. I asked him what he thought and his answer was simple. "I just sucked yesterday but it's not going to happen again." On the other side was a list of power values showcasing his best moments at this year's Tour. I showed him the numbers and he once again proclaimed, "I'm the best guy here. Today, I'm going ape shit. Today, I'm going to win."

We took his weight. I told him good luck then headed off for the finish. But he's never really needed luck or any sentimental "Chicken Soup" for his soul to get over a bad day. Just a bit of humor to lighten the mood, loud music, a wide-open road with nothing to lose, and the unyielding belief that he's the best in the world. Well, whatever it takes, today he proved that he has it. Today he gave everyone a reason to believe.

- 5 hours 23 minutes and 36 seconds.
- Covering 200.5 kilometers (130 km alone in the wind).
- At a speed of 37.175 km/hr.
- Averaging 281 watts when moving for the whole ride and 318 watts over the last two hours.
- Averaging 324 watts while pedaling for the whole ride and 364 watts over the last 2 hours.
- At an average cadence of 89 rpm.
- Transferring 5,456 Kjoules of energy to his Cycleops PowerTap.
- Taking, no joke, a total of 70 water bottles (480 ml each) from the car to keep himself cool and hydrated.
- Attacking about a quarter of the way up the Col des Saisies for 30 seconds at 544 watts, which settled into a 5-minute peak of 451 watts, which continued for 10 minutes at an average of power of 431 watts, and left everyone in his dust after 30 minutes at an average power of 401 watts.
- Spending 13.2% of his time or 43 minutes coasting like a rocket on the descents and another 60% between 4 to 7 watts per kilogram of body weight (aka, the pain cave).
- Holding onto 373 watts over the Col de Joux-Plane.
- Hitting a max speed of 83.7 km/hr (51.9 mph) and flying like a Phoenix on his way to the most incredible moment in sports I have ever witnessed.

Bicycling

Powerfeed Stage 18: The Race Isn't Over Yet

The last 24 hours have literally been the busiest of the Tour as Floyd prepares for the final time trial

By Allen Lim PhD

It was another hot day today and Floyd didn't do anything but hang out in the peleton, eat, and drink. Call it 200 km of fueling up for the final throw down of the Tour. So there's really not that much to report. The power file looked like a stroll in the park compared to yesterdays data and though Floyd was feeling tired this morning, today's ride wasn't bad for recovery. If only the bad day was today. After yesterday's amazing ride, it's almost better that things worked out the way they did. Well, maybe not. But, sometimes you never really know what you're made of until you've hit bottom.

Which, of course, brings me back to yesterday. I can't stop thinking about it. This morning I talked to Floyd about the day and he was still beaming from it. As we reviewed the data, both of us were impressed at the level of effort the day required. At the same time, however, we both also realized that the ride was well within his capacity. That he had done rides this big in training. Yes, it was a truly amazing effort, but both of us already knew how strong he is. The day was special because he finally got to show the world that strength. He found himself again and he never stopped believing. That's how he won that race. It was because he believed and no one else did.

With that in mind, I'd thought it'd be interesting to share a few more stats from yesterday -- specifically, the power outputs on the climbs.

Col des Saisies (6.4%): 395 watts in 36:55.

Col des Aravis (7.1%): 371 watts in 16:49.

Col de la Colombiere (5.8%): 392 watts in 27:45.

Cote de Chatillon-sur-Cluses (4.9%): 374 watts in 11:07.

Col de Joux-Plane (8.5%): 372 watts in 37:34. As a point of reference, these power outputs were very similar to the average power outputs over the 5 climbs on Stage 11 where Floyd first took yellow. More interesting, is the fact that over the course of the Tour, Floyd's best power output for 10-minutes didn't actually happen in the race. It actually happened on Monday's rest day when he decided to open it up on a hill near the hotel and cracked 460 watts. He was doing similar efforts in training before Georgia and before the Tour. So long story short, the conservative first two weeks was, in hindsight, not really true to his talent or style and I'm certain that this will be the last time we see Floyd do what everyone thinks he's suppose to do.

Now everything hinges on the time trial. While we are all confident that he will rage tomorrow, we're not taking anything to chance. This evening we had what looked like every engineer from BMC working on Floyd's time trial bike. It is truly impressive the quick and superb work these guys have done to re-spec Floyd's bike since the UCI rule change that forced him to lower his bars and the accident in the first long time trial. In addition to the bike, the directors drove the course tonight and it looks like the first 10-15 km is fairly technical, the middle 20-25 km is where most of the time will be made, and the final 10-15 km is fairly flat to downhill which will tend to keep the time differentials low. Floyd will be pre-riding the course in the morning to take a look for himself. In the meantime, we've got different pacing models built up for each 5 km section and have some pretty good idea about what he'll be able to hold and need to hold for Yellow. This thing isn't even close to over yet and the last 24 hours have literally been the busiest of the Tour. This staff has really rallied behind Floyd's incredible ride and we'll be doing everything we can to ensure he has the best ride of his life. What we all know though is that tomorrow he'll be carrying us. Like I said at the beginning of this Tour, "this guy is going to win the Tour."

Bicycling

Powerfeed Stage 19: Thanks Floyd

What you'll suffer through to make the dream happen

By Allen Lim PhD

As much as we all believed that Floyd would win, when he crossed the line today I couldn't believe it was happening. The moment was so unreal, so unlike anything I was prepared for, and at the same time so normal and expected. It left me in a daze. It's really difficult to try and express how everyone feels, how I feel. Of course, we're all happy, relieved, and excited. But I'm also feeling exhausted and pensive. It has been such a long and hard road to get here. Many, many bad days - more than just the one Floyd had last Wednesday. Now all balanced by this Yellow prize. Last year our joke was that the Tour was 99 One, which stood for 99% bullshit, 1% pure magic. We've been living and working for the magic ever since and it really does feel great to turn all that crap into gold. A lot better than losing, I'll tell you that much. But I can't help ignoring the other 99 right now. Because it was all that misery to get here that makes it worth it.

We were up at 6 this morning. No change in the routine. Gisbert squeezed fresh orange juice, just like he had every morning of the Tour and brought out a bucket of muesli. The pasta was made, eggs scrambled, and chocolate croissants spread out. Floyd was again, the first one at breakfast. The room felt really quiet, the way it does when the world isn't quite up yet. We talked more about the power he did on Stage 17 and Floyd got a kick out of it. I told him that I thought he'd do a 1:08:40. He thought it was too fast. By 7:45 am, we were out the door to check out the time trial course.

Keeping with tradition, Robbie Ventura and I joined Floyd to pre-ride the course. Floyd was in a great mood, just happy to be on his bike. It rained, but it didn't change how much fun we were having. We were like kids riding our bikes -- very far from the seriousness of the day ahead. Along the course the fans were already out in force and it wasn't even 8:30 am. As we rode along, everyone on the side of the road lit up with "Allez Floyd," or "C'est Landis." It gave me goose bumps. He's become an overnight legend here in France.

After the ride, Floyd headed back to the hotel for food and a nap. At 3 pm, he was back at the start. The warm-up wasn't hard. He kept it light so that he wouldn't get overheated as the day was already getting close to Popsicle sucking hot. He used an ice vest, drank water and an electrolyte-glucose drink, had two gels, and listened to "Fist of Rage" by Kid Rock many times.

For his Tour winning performance, I estimate his average power output at 394 Watts, about 3.5% better than he did in the final time trial last year, but not as strong as the 410 Watts that he unleashed on the first time trial. It was plenty.

When we got back to the hotel, the champagne, beer, and I don't know what started flowing like a damn broke. The mechanics broke out in song while putting yellow handlebar tape on all the bikes and everyone got busy congratulating each other.

I didn't want to miss dinner (as I normally have been to do these stories), so I found an empty room to get this written as quickly as possible. In the middle of putting this piece together, I was surprised to see Floyd side step the celebration outside and join me and my brother who flew in yesterday to help me keep my shit together (it's been a brutal Tour). Floyd was feeling the same way I was. Dazed and perhaps even sad that it's all over. I asked him what he was thinking and how it felt to put on that Yellow jersey. His reply was that he thought that maybe the process was more fun than the victory. It was the most sentimental thing I think I've heard him say all month. I asked, "You think the 99 is better than the One?" He replied, "It's never the same as you imagine."

So maybe it's not all the misery that makes getting here worth it. Maybe we just love the misery - the process of believing so deeply in your dreams that you'll suffer through anything to make them come true. After all, "passion" is to suffer. We've arrived and it really is magical. These memories are searing in my mind like a hot iron. And Floyd is truly the happiest and the proudest I've ever seen him. But there's no way we're putting it in park now. We can't. Cause time just keeps moving forward and though we have no idea what lies ahead, we have no choice but to follow. A new era has begun and a new road lies ahead, once again expectant and impatient. So before we start moving again, before the trucks get packed up and start their way towards Paris and the inevitable future, I just have to say thanks. Thanks Floyd. You've made my dreams...you've made all of our dreams come true.

Bicycling

Powerfeed Stage 20: Just Believe

Floyd is officially the Tour champ, let the party and the thanks begin

By Allen Lim PhD

It's a mob scene here. I can't get anywhere near Floyd right now, let alone his bicycle, so I'm going to file this last report without checking out his victory day stats. What I can tell you is that last year, he averaged 164 watts. I'm willing to bet that today's power profile was exactly the same as last year's for this stage. The only difference is that this year, he's the winner...I told you so.

I'm about to head off to the team party right now so I need to keep this short. In time, I think I'll be able to find the words to express all the emotion that this win has created for myself, Floyd, and the huge team of riders, staff, family, friends, and fans that made this all possible. Right now, I'm just too exhausted to put it into words. So for now I just want to say thanks to anyone and everyone who ever lifted a finger for us. We are indebted to so many people. At the hotel today, seeing all the family and friends who have come into Paris to greet all the riders made that point obvious and clear.

Although the list of people to thank is way too extensive, and I will probably screw this up, I have to thank David Cathcart and CycleOps Power as well as Robbie Ventura for connecting me with Floyd, and starting this crazy ride more than a year and a half ago. Of course, to my friends and family who were always unconditional in their support even if they never really understood what it was I did or whether or not it was a real career. Not to scare you, but I still haven't figured that one out yet. Thanks, to everyone on the TIAA-CREF Cycling Team and all the athletes/students/friends who have taught me more than I could ever teach. In particular, to Michael and Dede Barry, Christian VandeVelde, Alex Candelario, Jesse Bartholomew, and Dr. Shannon Smith - you guys kept me in this game at times when I was ready to pack up and fly home. And finally, to Dr. William Byrnes, my mentor at the University of Colorado at Boulder - not a day went by at this year's Tour that I didn't hear your voice in my head, forcing me to rethink, re-analyze, and suffer over every statistic, idea, or bit of advice I gave Floyd. Thermoregulation...how cool is that.

All of you had one thing common. You all believed. Floyd believed and he made me believe and we all believed together. For a science guy, I have to say, that was the best leap of faith I've ever made. Just believe...anything is possible.

Dr Brendan M Buckley FRCPI FFPATH FFSEM

Dr Una May,
Anti-Doping Unit,
The Irish Sports Council,
Block A, *Top Floor*,
West End Office Park,
Blanchardstown,
Dublin 15.

09 June 2006

Dear Dr May

Re:

The analytical findings on urine of an athlete sampled out of competition on September 30th 2005 and analysed in the Drug Control Centre of King's College London and therein coded A382195.

Dear Dr May:

The Authorised Expert Group, convened by the Irish Sports Council to consider the analytical findings detailed above, met on 5th May 2006 and subsequently further considered the data provided to us by the ISC. These data include the results of analysis of three prior and two subsequent urine samples from the same athlete.

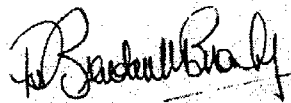

The Authorised Expert Group, having regard to the abnormal results of the tests on sample coded A382195 as well as their relationship to the normal results of prior and subsequent samples, considers that

1. The results deviate significantly from the range of values normally found in humans.
2. Are unlikely to be consistent with normal physiological endogenous production.

3. Are unlikely to be consistent with endogenous production due to a pathological state such as a congenital abnormality of androgenic steroid production, or an androgen-secreting tumour, or any other known pathological condition.

We therefore advise that we concur with the conclusions stated by Professor Cowan in his report of 28th April 2006 to you that the urine sample obtained by you on September 30th 2005 and analysed in the Drug Control Centre of King's College London and therein coded A382195 contained an abnormal concentration of testosterone, consistent with the administration of testosterone or of a substance that raises the concentration of testosterone.

Yours Faithfully

Dr Brendan M Buckley

Stable Isotope CF Analysis Results

File: DATA_008.raw
Project: controle2007.PRO
Sample list: 1704.spl
Line: 15
MS file: M-AN41
Inlet: GC-combustion
Inlet file: M-AN41
Sample ID:
Description: Calibration Mix Cal Acetate 001C

Acquisition Date: 31-7-2006 12:10:2
Weight: 0.00
Injection Volume: 10
Bottle:
Type:
Standard:
Slot Number: JB 251
Run Index:

| Reference standard | | | | | Corrections |
|-----------------------------------|--------|----------|--------|------|------------------------------|
| Species: CO2 by CF (uncalibrated) | | | | | Equilibrium correction: None |
| Gas: CO2 Uncalibrated CO2 | | | | | |
| Ratio type: Elemental | | | | | |
| Deconvolution: Craig | | | | | |
| Elemental delta | | | | | |
| Molecular delta | | | | | |
| Label: | Value: | Label: | Value: | wrt: | |
| Ratio 1: 13C | -34.5 | delta 45 | -32.93 | PDB | |
| Ratio 2: 18O | -19.3 | delta 46 | -19.35 | PDB | |

| Peak No | Major Height (nA) | RT (Sec) | Ratio 45/44 | Ratio 46/44 |
|---------|-------------------|----------|-------------|-------------|
| 1 | 1.83 | 42.8 | 1.1777E-02 | 4.2513E-03 |
| 2 | 1.64 | 102.6 | 1.1776E-02 | 4.2514E-03 |
| 3 | 7.22 | 162.6 | 1.1779E-02 | 4.2502E-03 |
| 4 | 7.23 | 222.7 | 1.1779E-02 | 4.2502E-03 |
| 5 | 3.90 | 282.7 | 1.1778E-02 | 4.2516E-03 |
| 6 | 3.88 | 342.7 | 1.1778E-02 | 4.2510E-03 |
| 7 | 10.10 | 402.8 | 1.1778E-02 | 4.2493E-03 |

REPROCESSING OF ELECTRONIC DATAFILES

Chatenay-Malabry (Paris, France) May 4-5 2006

Summary of Operation

On May 4th 2007, at 1.00 pm, technical experts of Mr Landis and of the USADA have met in the presence of an independent expert of the Panel at the Laboratoire National du Depistage du Dopage (LNDD) in Chatenay Malabry, to carry out the reprocessing of the Electronic Data Files (EDFs) copied on April 26th 2007.

The following people were present:

Dr. Simon Davis (scientific expert of Mr. Landis),¹ Dr. Thomas Brenna, Dr. Jeanine Jumeau (scientific experts of the USADA), Dr. Jacques de Ceaurriz (Director of the LNDD), Dr. Corinne Buisson (Responsible for the IRMS Department of the LNDD) Dr. Francesco Botrè (Independent expert for the Panel).

Before proceeding with the re-processing of the EDFs, Drs. de Ceaurriz and Buisson were asked to supply additional information on the process of backup of electronic data, either in general and with specific reference to those data copied on the three CD-ROMs on April 26th 2006 and still under the custody of the independent expert of the Panel. This mainly to further clarify the meaning of the following statement, reported at page 1 of the document "Copy of Electronic Datafiles – Summary of Operation" dated April 26th 2007:

"The datafiles of the IRMS analysis of the "A" and "B" sample of stage 17 were not copied directly from the hard disk of the instrument, but from a CD-ROM on which they had been previously backed up, as part of the internal procedures of the laboratory, by the personnel of the LNDD."

The following information was obtained:

- The process of backup of the datafiles from the internal memory of the old Isoprime (S.N. JA 010), i.e. the instrument on which the instrumental analysis of the "A" and "B" samples of stage 17 was performed, is periodically carried out manually, under the responsibility of the LNDD. In practice, these operations are performed by an external company that has a specific contract with the LNDD.
- Specifically, the original backup of the data concerning the analysis of the "A" and "B" samples of stage 17 was carried out on October 31th 2006. This is the process that was performed by removing the internal hard disk of the instrument, connecting it to a PC with a CD-writer and then re-installing the hard disk back in place inside the instrument. The data were stored on two CD-ROMs, labelled as "Backup du 31/10/2006 Data: 010206 → 251006 CD1" and "Backup du 31/10/2006 Data: 010206 → 251006 CD1". These are to be considered the two "master" CDs.
- The data stored on the two above mentioned master CDs were then copied, for practical reasons (i.e. to allow a faster retrieval of information), on more, additional CDs. Particularly, the data concerning the analysis of the "A" sample of stage 17 had been archived, together with other data files, also into another CD, labelled as "Isoprime I Data Juin 06 à 31/07/06 (créé le 30/01/07)".
- Finally, the data concerning the analysis of the "A" and "B" samples of stage 17 were also copied on another CD, labelled as "Isop 1 23/07/06 04/08/06"; this last CD, produced in the morning of April 26th 2007, contained only the data of the

two samples without any additional data (e.g. those of the assays to assess the linearity).

- The CD labelled as "Electronic Data Files Stage 17 A+B + Linearity", produced in the afternoon of April 26th 2007 at the presence of the technical experts of the Parties and of the independent expert of the Panel, contained copies of files stored on both the CD labelled as "Isop 1 23/07/06 04/08/06" (data files of samples "A" and "B" of stage 17) and on the CD labelled as "Isoprime I Data Juin 06 à 31/07/06 (créé le 30/01/07)" (data files of the linearity assays).

The above back-up history was documented by obtaining hardcopies of the list of folders/files stored on each one of the above mentioned CD-ROMs.

Prior to begin the extraction of the EDFs, the Parties discussed on which were the files to be reprocessed, whether only the files of the sample (A and B) collected on the occasion of the stage 17, or also those referring to the 10 blind "B" samples analyzed by GC-IRMS in the period from April 17th to April 22nd 2007. The discussion also involved the request of Mr. Landis' expert to access the logfile copied on the CD-ROM labeled as "Logfile" on the occasion of the previous meeting at the LNDD, on April 26th 2006. According to the instructions received by the President of the Panel, Mr. Patrice Brunet, in his email message of May 3rd 2007, Dr. Botrè tried without success to contact by phone Mr. Richard Campbell, and left a message on his mobile phone voicemail. In order to optimize the timeframe of operation, it was agreed to go on anyway with the reprocessing of the EDFs of the "A" and "B" samples from stage 17 first, and to go back to the issue of the 10 blind samples datafiles and of the logfile later on.

The sealed envelope containing the CD-ROM labelled as "Electronic Data Files Stage 17 A+B + Linearity" was then opened by Dr. Botrè and, at 3.05 pm, all present moved from the meeting room to the laboratory room hosting the GC-IRMS instruments.

The reprocessing of the EDFs was first performed on the same instrument used for the original analysis of the "A" and "B" samples of stage 17. The process was performed in the presence of Drs. Davis, Brenna, Juneau, Buisson and Botrè, while Dr. de Caurriz was not constantly present in the GC-IRMS room.

To carry out the reprocessing of the files it was necessary to copy back the files from the CD to the internal memory of the instrument. It was indeed not possible to load and reprocess the data directly from the CD-ROM. Two new folders ("230706" and "040806") were then created on the internal memory of the instruments, and the relevant files were copied inside these two folders from the CD-ROM. A printout of the list of folders contained in the data directory of the internal hard disk of the instrument was produced immediately before and right after the copying process took place.

Once the files were copied, it was possible to start with their reprocessing. It was agreed that an analyst of the LNDD (namely, the same person who originally processed the data on the occasion respectively of the "A" and "B" analysis, according to the information reported on the Laboratory Documentation Packages) would have operated the computer to carry out the reprocessing of the datafiles, under the responsibility and at the presence of the independent expert of the Panel and at the presence of the experts of the Parties.

It was agreed that three outputs had to be produced for each file: (a) a first one, applying the automatic subtraction of the background; (b) a second one, manually

subtracting the background; (c) a third one, with no background subtraction. Each output consists of two pages, a data page ("Data Processing Results") and a graphical page. The output of each file is then represented by 6 (six) printed pages.

It was agreed to start with the reprocessing of the datafiles of the "A" sample, i.e. with those copied in the folder "230706".

The reprocessing of the files started at 3.45pm. The reprocessing of the datafiles of the "A" sample was completed without comparing the outputs with those reported in the Laboratory Documentation Packages.

At 7.00pm, it was agreed to suspend the operation to continue on the following day.

It was agreed to delete the files (both those just reprocessed and those still to be reprocessed) copied on the internal hard disk of the instrument. A printout of the new list of folders in the data directory was also produced.

The operations ended at 7.30pm. It was agreed to continue the operation on the following day, May 5th, at 9.00am.

The operations started again at 9.15am on May 5th 2007. In a preliminary meeting, it was agreed to complete the process suspended the day before. All the presents moved again to the laboratory room hosting the GC-IRMS instruments at 9.30am. The files not yet reprocessed were copied again on the internal hard disk of the instrument.

The above files were then reprocessed, starting with the EDFs of sample "B", then proceeding with the two sets of the stability runs (one for the "B" and one for the "A" sample), and with the two sets of linearity runs originally performed on June 26th 2006 and on July 31st 2006. Also in this case the reprocessing of the datafiles was completed without comparing the outputs with those reported in the Laboratory Documentation Packages.

After all the above processes were completed, the data were deleted again from the internal hard disk of the instrument.

At 11.20am it was agreed to start the reprocessing of the EDFs on the new instrument. The conversion of the files was carried out by Dr. Buisson, under the supervision of the independent expert of the Panel and at the presence of the technical experts of the parties. A new directory ("Reprocessing050507") was created on the internal hard disk of the instrument and the procedure outlined in the document "07-04-29 EDF Instructions to Dr. Botrè" was followed. The files were successfully converted and saved into the new directory; nonetheless, it was not possible to reprocess them.

Davis explained that this could be due to the lack of some "support" files that are automatically generated during the analysis of real samples and that, consequently, were not present in the new directory. To proceed with the reprocessing of the datafiles, it was agreed to copy, from other data directories into the newly created directory, also those support files. This procedure allowed to open the files under the software of the instrument and to reprocess them for the first time by this instrument.

It was agreed reprocess all those files that had just been reprocessed by the original instrument. The reprocessing of the files was carried out by the same two analysts who had just reprocessed the data on the original instrument.

The file were reprocessed following the routine procedure of the laboratory for the analysis of real samples. Two printouts were produced to show the routine processing parameters of the laboratory, which were applied also for the reprocessing of the datafiles.

It was possible to complete the reprocessing of all files, apart from the datafile "data010" (respective to the blank urine fraction 3 of the "B" analysis), for which an error message appeared. This is documented by two printouts of the screenshot.

At 1.45pm the reprocessing of the datafiles on the new instrument was completed. All the presents left the GC-IRMS laboratory and went to the meeting room.

At this point, Dr. Davis stated that the reprocessing of the datafiles of the 10 blind samples was no longer necessary. It was therefore agreed not to open the sealed envelope containing the corresponding CD-ROM, which remained under the custody of the independent observer. It was no longer necessary to contact the Panel for this issue.

With respect to the issue of the logfile – copied on the CD-ROM labelled as "Logfile" on April 26th 2007 – Dr. Botrè felt it necessary to ask for the opinion of the Panel, also to decide whether or not to supply copies of the printouts produced during the 2-days operation to the Parties. To this respect, Dr. Botrè repeatedly tried to contact – sequentially – Mr. Campbell, Mr. McLaren and Mr. Brunet, without success. At around 15.35pm Mr. McLaren called back. The following indications were supplied to Dr. Botrè: (1) the Parties could be given copies of the printouts, provided it was possible to clearly mark all the copies as originals; (2) it was also agreed that it was not possible to printout the content of the logfile and to give it to the Parties its entirety, since it contained confidential information regarding the activity of the lab for samples other than Mr. Landis'. It was agreed to cut-and-copy only the portion regarding the six days (April 17-22) in which the analysis of the 10 blind samples took place.

A total of 206 printed pages (numbered from 1 to 206) were produced during the two-days of operation. The original copy is under the custody of Dr. Botrè. The other three copies, with every page stamped in red as "Copie certifiée conforme des données et formulaires originaux", were distributed to the Parties and to the LNDD.

The operation ended at 5.20 pm.

Chatenay-Malabry, May 5th 2007.

Le Tour 2006: Daily Analysis Report

Stage: **Strasbourg to Strasbourg, 184.5 km** Sunday, July 2nd

Floyd Landis

Temp: 84 °F / 29 °C Humidity: 45 % Heat Index: 84.1 °F / 28.97 °C

Stage Results: 184.5 km 44.3 km/hr 27.3 km/hr

GC Results: 179.6 km 35.0 km/hr 44.3 km/hr 27.3 km/hr

Place: 46 Time: 4 hrs 10 min 0 sec Gap: 0 min 0 sec

Place: 9 Time: 4 hrs 18 min 26 sec Gap: 0 hrs 0 min 9 sec

Race Notes: Today the guys just cruised. It was on the warm side and the racing was a bit nervous but all in all it was a pretty chill day for all involved. No comment from Floyd except that it was really easy.

Race Notes: Today was really similar to yesterday. Floyd felt it was really easy, except for the fact that it felt a lot hotter today despite the temperature not actually being that different. Lots of solar radiation. Seemed like more work on hills. Floyd says he drank 20 bottles. Forgot weights. No GPS.

Le Tour 2006: Daily Analysis Report

Stage 1: Esch-Sur-Alzette to Lulenburg, 216.5 km

Tuesday, July 4th

Floyd Landis

Temp: 95 °F / 35 °C Humidity: 45 % Heat Index: 102 °F / 38.83 °C

Stage Results: 216.5 km 43.6 km/hr 21.2 mph

GC Results: 630.6 km ridden 42.5 km/hr 26.1 mph

Place: 44 Time: 4 hrs 57 min 59 sec Gap: 0 min 5 sec

Place: 7 Time: 14 hrs 52 min 39 sec Gap: 0 hrs 0 min 16 sec

Race Notes: Today was super hot. John says the temp from the car read 37 °C. It was also really up and down today with much harder efforts for all of the riders. We rode through Bastogne and into Liege today as well. Historic stuff.

Le Tour 2006: Daily Analysis Report

Stage 11: Tarbes au Val d'Aspin (Pla-de-Beret) 206.5 km

Thursday, July 13th

Floyd Landis

Temp: 71 °F / 22 °C Humidity: 60 % Heat Index: 75.9 °F / 24.41 °C

Stage Results: 206.5 km 35.2 km/hr 21.0 mph

ACC Results: 1:29:00 American km/hr mph

Place: 3 Time: 6 hrs 6 min 25 sec Gap: 0 min 0 sec

Place: 1 Time: 49 hrs 18 min 7 sec Gap: 0 hrs 0 min 0 sec

Race Notes: Floyd rode brilliantly today. Looked really at ease and patient. Finished third with Menchov and Levi. In Yellow. Amazing. Power profile looked good. Well within Floyd's limits. Best 30 s, 1 min, 5 min, and 10 min on Col de Portillon. Best 30 min on Beret.

Le Tour 2006: Daily Analysis Report

Stage 12: Bagnols-Montclair, 230 km

Saturday, July 15th

Floyd Landis

Temp: 95 °F / 35 °C Humidity: 60 % Heat Index: 113 °F / 45.05 °C

Stage Results: 230.0 km, 38.9 km/hr, 24.1 mph

GC Results: 1,440.0 km ridden, 40.8 km/hr, 25.3 mph

Place: 29 Time: 5 hrs 54 min 33 sec Gap: 29 min 57 sec

Place: 2 Time: 59 hrs 52 min 3 sec Gap: 0 hrs 1 min 2 sec

Race Notes: It was so freaking hot today. Way too hot to do anything except nothing. Why was it so hot. Peirero and Voight and Chaval, and

some other guy got away and built a 30 minute gap. Floyd gives up yellow. Super easy. That's a good thing. Time to get some rest the next two days.

Le Tour 2006: Daily Analysis Report

Stage: 15: Gap to L'Alpe d'Huez, 137 km

Tuesday, July 18th

Floyd Landis

Temp: 90 °F / 32 °C Humidity: 60 % Heat Index: 99.7 °F / 37.6 °C

Stage Results: 137.0 km 39.2 km/hr 23.7 mph

GC Results: 2,614.0 km 39.2 km/hr 23.7 mph

Place: 4 Time: 4 hrs 53 min 32 sec Gap: 1 min 10 sec

Place: 1 Time: 69 hrs 0 min 5 sec Gap: 0 hrs 0 min 0 sec

Race Notes: Floyd had the broken axle today and the mechanics forgot to switch out the computer with the wheel change. So we lost data.

This report is for the first 100 km and the other is calculated off of the math model.

Confirming testosterone administration by isotope ratio mass spectrometric analysis of urinary androstenediols

Cedric H.L. Shackleton,* Andy Phillips,† Tony Chang,* and Ye Li‡

*Children's Hospital Oakland Research Institute, Oakland, California, USA; †Micromass UK Limited, Manchester, England, UK; and, ‡National Research Institute of Sports Medicine, Beijing, China

A gas chromatographic combustion isotope ratio mass spectrometric (GC/C/IRMS) method was used for studying the incorporation of exogenous testosterone enanthate into excreted urinary 5 α - and 5 β -androstane-3 α ,17 β -diols. A multistep but straightforward work-up procedure produced a simple GC chromatogram of urinary steroid acetates composed principally of two androstenediols and pregnanediol. It is anticipated that such a method may form the basis of a doping control test for testosterone that could be used as a primary method during major sporting events or alternatively as a verification technique. Urine samples from five individuals were collected before and after administration of testosterone enanthate (250 mg). The $\delta^{13}\text{C}$ ‰ value of androstenediols was around -26 to -28 during the baseline period and decreased to about -29 to -30 in the days following synthetic testosterone administration. One of the other major steroids in the chromatogram, pregnanediol, was utilized as the "internal standard," because its $\delta^{13}\text{C}$ ‰ values did not markedly change following testosterone administration, remaining at -25 to -27. In all subjects studied, the $\delta^{13}\text{C}$ ‰ values for androstenediols were reduced sufficiently over 8 days to confirm administration of synthetic testosterone. Although steroids isolated from urine of normal individuals from 12 different countries gave values between -24 and -28, this seemed not to be related to nationality or region. The most likely variable is the proportion of plants with low and high carbon 13 content in the diet. This variable is likely to be more affected by individual food preferences than broad ethnic food divisions. In this paper, we propose a ratio of $\delta^{13}\text{C}$ ‰ for androstenediols to pregnanediol as a useful discriminant of testosterone misuse, a value above 1.1:1.0 being indicative of such misuse. The work-up procedure was designed for batch analysis and to use only simple techniques, rather than employ further instrumentation, such as high-performance liquid chromatography (HPLC), in purifying steroids for GC/C/IRMS. Keywords: isotope ratio mass spectrometry (IRMS); doping control; testosterone

Introduction

The increasing need in sport for proving testosterone misuse requires new methodologies. For many years, a testosterone/epitestosterone (T/E) excretion ratio determined by gas chromatography-mass spectroscopy (GC-MS) of greater than 6:1 has been used as the hallmark for confirmation of drug administration,¹ but this method is fallible. For one thing, occasional drug-free individuals give a ratio >6, and

a high ratio can also be adjusted downward by simultaneous administration of epitestosterone. We have found that in eight Chinese subjects given 250 mg testosterone enanthate, only three gave T/E values >6 on more than 1 day, demonstrating a high rate of false negatives, at least in this racial group.

In 1990, Southan and co-workers² used isotope ratio mass spectrometry (IRMS) to show that synthetic testosterone had a different ^{13}C content than endogenous hormone. This is a reflection of the origin of the materials, because all testosterone, both endogenous and synthetic, is ultimately of plant origin. Gonadal testosterone is made from precursor molecules derived from a wide variety of vegetable mate-

rials eaten by humans or by the animals humans eat. Individual plants discriminate to different degrees against ^{13}C , and particular species are known to have high or low levels of ^{13}C in their biomolecules.³ In human bodies, the ^{13}C content, therefore, reflects an average of the ^{13}C content of all the plant material eaten by humans and our animal protein providers. Synthetic testosterone, in contrast, is generally made from a single plant species, mostly soy, so the ^{13}C content has a defined value reflecting the relatively low ^{13}C content of this plant. Thus, a significant difference in ^{13}C content between gonadal and soy testosterone could provide the basis for developing a definitive test for hormone misuse. Differences in carbon isotope ratios referred to by the symbol δ , defined as the difference in isotope ratio between the sample and an international carbonate standard "PDB." Although this is the accepted standard, for common usage a calibrated international standard of CO_2 is used. The values reported for δ carbon isotope ratios are

$$\delta^{13}\text{C}/\text{‰} = \left(\frac{\text{Ratio sample} - \text{Ratio PDB}}{\text{Ratio PDB}} \right) \times 1000$$

Becchi and coinvestigators have published pioneering studies on development of a method employing IRMS for determination of carbon isotope ratio of testosterone extracted from urine.^{4,5} They demonstrated that, providing sufficient urine was available, the endogenous or exogenous origin of testosterone could be readily determined. A major remaining problem demonstrated by these studies relates to sensitivity of the analysis, because the quantity of urine collected from athletes is relatively small (about 75 mL), and this is divided into two, a primary (A) and a secondary sample (B). On each sample, nonsteroidal drug metabolites must be analyzed, as well as anabolic steroid screening and measurement of the T/E ratio.

We have attempted to improve the methodology to allow more sensitive analysis. It was decided to forgo any attempt to analyze testosterone itself and to concentrate on analysis of its metabolites 5 α -androstane-3 α ,17 β -diol (5 α AD) and 5 β -androstane-3 α ,17 β -diol (5 β AD). Our overall objective was to easily produce a single sample for analysis containing a few defined steroids to include the androstanediols and steroids we call "endogenous reference compounds" (ERCs). An ERC, in this instance, is a steroid whose carbon isotope ratio could not be altered through administration of exogenous testosterone. Aguilera, Becchi, and co-workers in their most recent publication use cholesterol and 5-androstene-3 β ,17 β -diol as ERC.⁵ To achieve our overall objective, we developed simple methodology adaptable to batch analysis, which required no liquid chromatographic (HPLC) instrumentation. Using this methodology, we determined the $\delta^{13}\text{C}/\text{‰}$ of the androstanediols present in urine following administration of testosterone enanthate to five volunteers. This communication presents the results of this study.

Experimental

Materials

Testosterone enanthate, Testoviron depot® was obtained from Schering, Japan. Reference steroids were obtained from Sigma (St.

Louis, Missouri, USA), which was also the supplier of Girard reagent T (carboxymethyl, trimethyl ammonium chloride hydrazide) and sodium bismuthate. Sephadex LH 20 was a product of Pharmacia AB and Sep-pak® cartridges, a product of Waters Corp. (Milford, Massachusetts, USA). β -glucuronidase/aryl sulfatase was obtained from Sigma (Type H1) and Boehringer Mannheim (Mannheim, Germany). Solvents were of analytical grade.

Individuals studied

Eight Chinese male subjects aged 19–22 were studied, although GC/C/IRMS analysis was only conducted on five. Permission for undertaking these experiments was obtained from the Chinese National Research Institute of Sports Medicine, and consent was obtained from the participants. Spot morning urine samples were collected for 2 days prior to an intramuscular injection of 250 mg testosterone enanthate. Two urine samples (0–8 h and 8–24 h) were collected for the first 4 days after administration, although only aliquots of the early morning sample were subject to analysis. Morning spot urine samples were collected on the 5–9th days after administration and on days 11, 13, and 15.

Determination of testosterone/epitestosterone ratio (T/E)

Urinary testosterone and epitestosterone were quantified in all the samples using an adaptation of the method of Donike et al.⁶ These measurements were carried out by one of us (YL) in China at the National Institute of Sports Medicine. T/E ratios were then determined.

Preparation of steroid extract for GC/C/IRMS

A flowsheet summarizing the methodology is shown in Figure 1. Urine (typically 25 mL) was extracted by Sep-pak® cartridge according to the method of Shackleton and Whitney.⁷ Once dried, the extract was dissolved in 3 mL 0.1 M acetate buffer pH 5 and *Helix pomatia*-derived β -glucuronidase/sulfatase (12 mg Sigma

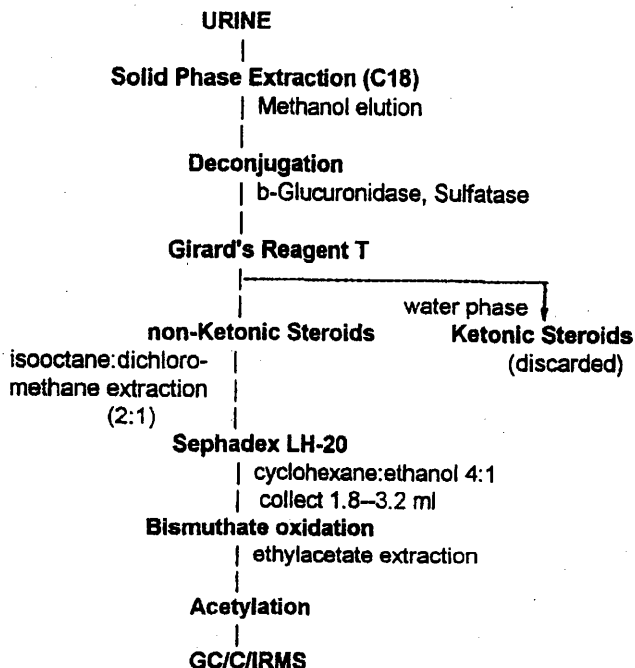

Figure 1 Flow sheet of the urinary extraction method.

type H1 powder, 100 μL Boehringer liquid enzyme) was added. Hydrolysis was allowed to proceed for 3 h at 55°C. A Girard separation was carried out to separate carbonyl-containing steroids (ketonic) from noncarbonyl-containing (nonketonic) steroids.^{8,9} To the hydrolyzed urine mixture, 2 mL glacial acetic acid and 100 mg Girard reagent T was added. The solutions were placed in an oven at 100°C for 30 min. The nonketonic steroids were extracted by 2 \times 5 mL isooctane: dichloromethane 2:1 (v/v), and the solvent was dried. Small columns of 0.5 Sephadex LH-20 were prepared in Pasteur pipettes, the Sephadex being allowed to swell in the cyclohexane: ethanol (4:1) solvent system before preparation.¹⁰ The steroid extract dissolved in 100 μL of the same solvent mixture was added to these columns. Solvent eluting between 1.8 and 3.2 mL was collected and dried. Acetic acid (0.1 mL), water (0.1 mL), and 5 mg sodium bismuthate were added.⁹ Oxidation was allowed to proceed for 2 h, and after neutralization (0.5 mL of 0.5 M acetate buffer), the mixture was extracted with 4 mL ethyl acetate. After drying, steroid acetates were prepared overnight with 50 μL acetic anhydride and 50 μL pyridine. The acetates were analyzed by GC/C/IRMS.

Gas chromatography combustion isotope mass spectrometry (GC/C/IRMS)

A schematic representation of the GC/C/IRMS instrumentation is illustrated in Figure 2. The acetylated steroid samples were kept refrigerated until analysis. Cyclohexane (20 μL ; 99.9% pure from Sigma Chemicals 27-0625-8) was added to each vial, and one-tenth (2 μL) of each sample was injected splitless onto a J&W 30 m DB17 capillary column housed in a Fisons 8000 series GC. The injector was kept at 220°C. The temperature program was as follows: starting temperature 50°C (1 min), followed by rapid temperature increase (25° min) to 300°C, where it was held for 15 min.

The separated components were heart-split into the combustion furnace filled with copper oxide wires (Elemental Microanalysis Limited, UK) held at 850°C. The combustion gases were passed through a nafion membrane water removal trap, and the remaining CO_2 was analyzed on a Micromass isochrom isotope mass spectrometer. The mass spectrometer consisted of an electron impact source running at 400 μA current, the ionized CO_2 gas, was focused by a magnet onto three Faraday collectors. The ions collected were those at masses 44, 45, and 46. The Micromass data system calculated the areas of the beams and subtracted any background; whereupon, calculation of the ^{13}C δ values for the successive peaks were carried out.

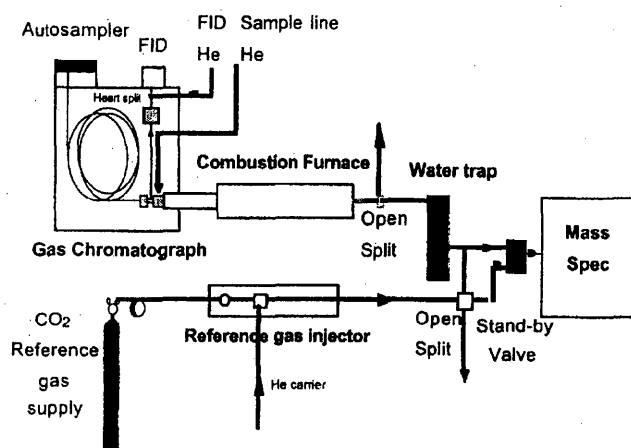

Figure 2 Schematic of the Micromass GC/C/IRMS instrument.

Results and discussion

Evaluation of gas chromatographic columns

The objective of the study was to measure $\delta^{13}\text{C}/100$ for urinary androstane diols formed as metabolites of testosterone. In our initial studies (Subject 1), we undertook chromatography on DB1 capillary columns but did not get resolution of the two diacetylated epimers (Figure 3A). Later employment of a DB17 column (Figure 3B) allowed separation of the epimers as well as the ERC, pregnane diol diacetate, and pregnane triol diacetate (Figure 3B).

Confirmation of identity of steroids in extracts

Prior to sending the first samples for GC/C/IRMS analyses in England, the identities of the principal components of the chromatogram were confirmed by GC/MS. This was carried out on a Hewlett-Packard 5970 instrument housing a 15 meter DB1 capillary column. The peaks chosen for GC/C/IRMS analyses had retention times and electron impact mass spectra identical to those of 5 α - and 5 β -androstane diol diacetate and pregnane diol diacetate. Reference steroids for these compounds were also analyzed on the GC/C/IRMS instrument using both DB1 and DB17 columns, and these gave identical retention times to the urinary steroids. Pregnane triol could also be analyzed by GC/C/IRMS.

Achievement of work-up procedure objective

The method developed and utilized had the following qualities. First, the Girard separation almost completely removed carbonyl containing steroids from the hydrolyzed extracts, which probably represent 75% of urinary steroids. Exceptions may be the 11-carbonyl containing steroids that probably do not react because of the hindered nature of that functional group. Second, a crude micro Sephadex LH-20 column separation effectively produced a fraction containing steroids with two and three functional groups. Third, sodium bismuthate oxidation was designed into the procedure as a means of removing remaining long-retention time pregnane metabolites, thus allowing shorter periods between injection. Many of the quantitatively more important metabolites are converted into 17-oxygenated C_{19} steroids by the procedure. Fourth, acetylation provided steroids with good gas chromatographic properties that were readily separated. Fifth, despite the complexity of the steroid fraction of urine, the final chromatogram was simple and composed of only a few peaks for which $\delta^{13}\text{C}/100$ could be determined with accuracy.

$\delta^{13}\text{C}/100$ value of the synthetic testosterone

Testosterone acetate prepared from the Japanese testosterone enanthate used for injection in these studies gave a $^{13}\text{C}/100$ value of -30.41 , a value close to the lowest value obtained for androstane diol diacetate measurements obtained in the subjects studied following testosterone administration.

We also analyzed five other current products and one synthetic sample made more than 40 years ago. The following results were obtained: testosterone of Chinese manufacture -30.40 ; U.S. manufacture -30.38 ; two Czech products,

Figure 3 Gas chromatographic separation (on GC/C/IRMS instrument) of acetylated urinary steroid fraction. This sample was initially separated on a DB1 column, which failed to resolve the 5 α - and 5 β -androstanediols (upper panel). Later employment of a DB17 column permitted individual measurement of the epimers (lower panel). Both columns also resolved etiocholanolone, produced by bismuthate oxidation of pregnanetriol, pregnanediol, and nonoxidized pregnanetriol.

–29.28 and –29.15, respectively; and one Russian –30.22. The U.S. sample of more than 40 years old gave a value of –33.18, probably reflecting the different plant origin of synthetic steroids made long ago. We believe that testosterone is currently made mostly from soy by-products, although originally sterol constituents of the Mexican yam were the primary precursors.

Results for individual subjects

With the exception of Subject 1, a DB17 capillary column was utilized that allowed separate analysis of 5 α - and 5 β -androstanediols. Graphs illustrating the $\delta^{13}\text{C}/100$ results are shown in Figure 4A–F. In all cases, the $\delta^{13}\text{C}/100$ values for

the androstanediols fell significantly following testosterone administration.

Figure 4 illustrates two other features. One is the adequacy of making single measurements of $\delta^{13}\text{C}/100$ for each sample. Panel B and C show results obtained by plotting the average of duplicate measurements (B) and of the *first* measurement of the duplicate pair (C). Essentially these graphs are identical, suggesting duplicate GC/C/IRMS analyses of the same preparative extract are unnecessary. The second feature relates to the trend of slightly increasing δ values for pregnanediol during the study period of Subject 3 (Figure 4D). Because this is not caused by random irreproducibility we proposed that the individual changed his diet substantially to foodstuffs with higher $\delta^{13}\text{C}/100$ values.

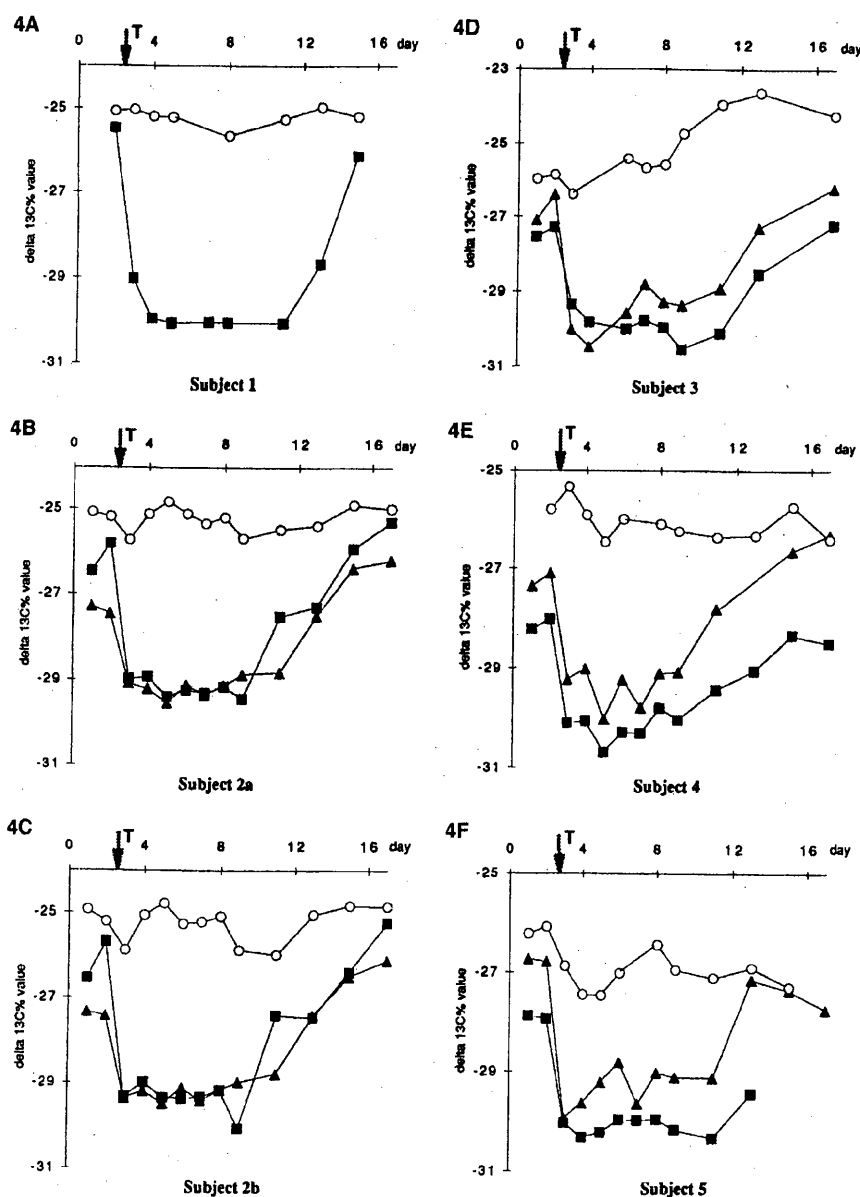

Figure 4 Values of $\delta^{13}\text{C}^0/00$ for all five subjects throughout the study period. The open circles represent pregnanediol, the closed rectangles 5 β AD and closed triangles 5 α AD. 4A shows the values obtained for Subject 1 in which only one baseline sample was analyzed, the testosterone being administered on the 2nd day of study. Both androstenediols were measured together on a DB1 column, 4B shows plots for Subject 2 obtained by averaging values for the duplicate runs, and 4C shows equivalent plots through only using the first analysis. 4C, 4D, and 4E are plots of Subjects 3, 4, and 5. For Subjects 2–5 the testosterone was administered after the second baseline sample (day 3 of study).

Designing a method for universal use demands final agreement of numerative values above and below which individuals are considered to have or to have not illicitly used a drug. In our studies with the Chinese subjects, it can be stated that for the five individuals, none had androstenediol $\delta^{13}\text{C}^0/00$ values less than -28.3 during the control period, and establishing a conservative cut-off value of -29.0 would clearly pick up all drug users for about 7 days after administration. Additionally, we considered that measurement of analyte/ECR ratios could allow numerative values to be established that are to some degree independent of variables introduced through using the methodology in different laboratories with different instrumen-

tation. In Figure 5A, we show the $\delta^{13}\text{C}^0/00$ ratio of combined androstenediols (average of 5 α - and 5 β -) to pregnanediol (PD) for the five individuals studied so far. All baseline ratios fell below 1.08, and from these data, we would suggest that a ratio of greater than 1.1 could be used to confirm testosterone administration. When we averaged the data for the five individuals, we found that the AD/PD ratio value of 1.1 was exceeded for 11 days (Figure 5B). Because a combined androstenediol measurement is carried out in the Aguilera et al. studies,⁵ comparable data could be prepared from their measurements, although in their case, cholesterol would be the ERC used for ratio determination.

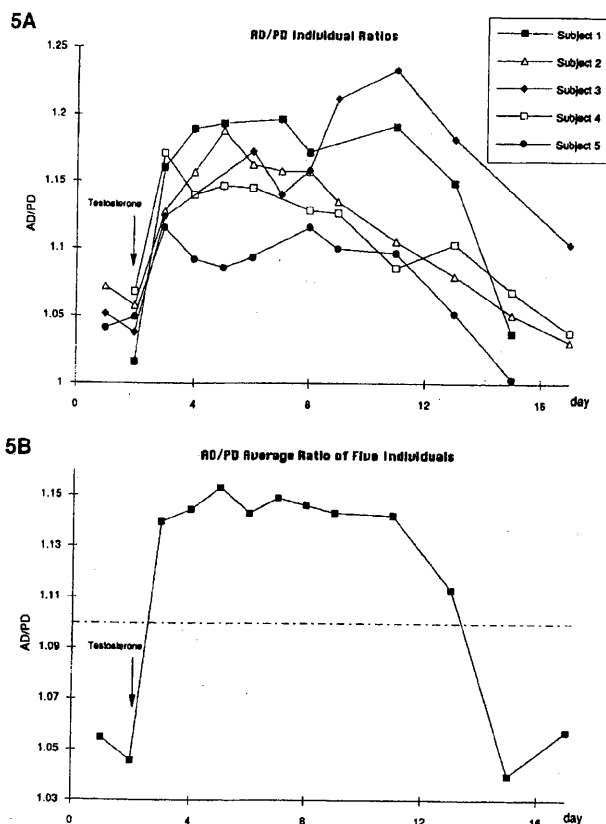

Figure 5 Androstanediol/pregnanediol ratio. A) ratios of $\delta^{13}\text{C}/00$ for the androstanediols (mean of 5α and β) to pregnanediol for the five subjects; B) average of the ratio for the five subjects for each day; the dotted line represents the proposed discriminant value (1.10) for confirmation of testosterone administration.

Reproducibility of isotope measurements and accuracy

For the five subjects studied, ideally 26 or more isotope measurements were made for each steroid; i.e., 13 duplicate analyses. A few samples were lost or contaminated, and occasionally only single measurements were made on a sample. As a representative analysis, Table 1 gives all of the measurements for Subject 2. Using these data, there are two features of accuracy and reproducibility that can be quantified. One is the variation in δ measurement between duplicate analyses of the same sample and the other the overall variation occurring during analyses of a complete series from one individual. For duplicates, the reproducibility was excellent and did not differ significantly between the five subjects studied. Considering the data shown in Table 1, averages and standard deviations were measured for each duplicate for the two androstanediol and pregnanediol diastereates that give values in the $\delta^{13}\text{C}/00$ -23 to -30 range. Means were then determined of the standard deviations. For pregnanediol, the mean standard deviation between duplicates was ± 0.21 with a range of ± 0.02 to ± 0.71 . Comparable results were obtained for the androstanediols (± 0.11 for 5α -androstanediol and ± 0.25 for 5β -androstanediol). These results were considered to represent excellent reproducibility and (as previously noted) suggested that the meth-

odology could be used with *single* determinations by GC/C/IRMS of $\delta^{13}\text{C}/00$ for each steroid. This was illustrated graphically in Figure 4B and C, which showed both the $\delta^{13}\text{C}/00$ values for the average of duplicates and for the first analysis. The graphs were essentially identical.

Within a 17-day series of datapoints for duplicate assays for a single individual, the results show considerably less reproducibility—notice the peaks and valleys of the pregnanediol plots in Figure 4. In any physicochemical analyses, it is, of course, possible to have excellent reproducibility but compromised values. For accuracy and reproducibility assessment between a series of different samples, we use the δ measurement of the ERC pregnanediol. The administration of testosterone should in no way change the $\delta^{13}\text{C}/00$ value for pregnanediol that has to be produced from cholesterol via several intermediates. In a perfect analysis, the measured ^{13}C content of pregnanediol would not be expected to change during the 17-day study period unless, of course, the individual alters his or her diet markedly during the study period. Even with dietary modification, the ^{13}C content of body molecular constituents would be expected to change only slowly.

The highest and lowest duplicate average $\delta^{13}\text{C}/00$ values for pregnanediol for the five subjects differed by -0.92 to -2.96 . As previously mentioned, with the exception of Subject 2, the average duplicate values seemed to rise and fall randomly during the 17-day study period. What

^aThe first collection following testosterone administration.

is the source of this irreproducibility? Because we know that the reproducibility of $\delta^{13}\text{C}/00$ measurements of individual steroids in duplicate GC/C/IRMS runs is excellent, we must assume that the measured $\delta^{13}\text{C}/00$ values for individual chromatographic peaks are accurate. If these are accurate, then any difference in the value from the "true" value for the steroid determined must represent some minor contamination of the steroid peak by components with greater or less $\delta^{13}\text{C}/00$ values. We have proposed that the trend to increasing values for Subject 2 may be because of dietary changes toward foodstuffs with greater ^{13}C content.

These minor irreproducibilities, which typically give rise to a range of about -1.5 in the δ value for all datapoints during the study period, will not affect the outcome of a drug test, because in no cases do the lowest values breach the discriminant value for the positives.

Testosterone/epitestosterone ratios

Table 2 gives the T/E values for five individuals studied here (Subjects 1–5) and three other subjects whose steroids were not analyzed by the IRMS technique (Subjects 6–8). The data show that the maximal increase in the ratio for each of the individuals was between 12 and 68 times baseline level, although it was noticeable that only 4 of the 8 subjects gave T/E values greater than 6 and 1 of these only modestly exceeded it on one occasion (T/E 6.69). The T/E ratio of the five subjects studied here have been included in Figure 5C as compared to the $\delta^{13}\text{C}/00$ AD/PD ratio for the same individuals.

$\delta^{13}\text{C}/00$ steroid values for different nationalities

Figure 6 shows the $\delta^{13}\text{C}/00$ values for duplicate analyses of the androstane diols and PD from 15 individuals of 11 different nationalities in addition to the Chinese. In some cases, it was possible only to obtain values for the 5β androstane diols because of the low amounts of 5α AD present. The results demonstrate that there are differences among racially and regionally varied individuals with undetermined diet, but we must remember that part of this variation may be attributable to the analytical inaccuracies previously discussed. However, all values were greater than -28.2 , which should be compared to the values of less than -29.2

Figure 6 The lower panel shows the $\delta^{13}\text{C}/00$ values for the androstane diols and pregnane diols for individuals of different nationality, while the upper panel shows the $5\beta\text{AD}/\text{PD}$ ratio. The open circles represent PD, the closed diamonds $5\alpha\text{AD}$ and closed rectangles $5\beta\text{AD}$. The baseline values for the Chinese represent the mean of the two measurements, while the Chinese "testosterone" values represent the average of the 7 days after drug administration. Pregnanediol was below detection level in the Chilean urine, so pregnanetriol values were reported instead.

found in the subjects studied following testosterone administration. The mean value for the $5\beta\text{AD}/\text{PD}$ ratio was 1.02 ± 0.03 with a range of 0.95 to 1.07, which compares to the average value for the Chinese baseline samples of 1.05 ± 0.03 (range 1.01 to 1.08). The ratio values for the testosterone administered subjects were all >1.15 in the first days after injection. These data support the previous cut-off ratio value of 1.1:1.0 suggested on the basis of studying the Chinese subjects before and after testosterone administration.

There are notable features with regard to the ^{13}C content

^aDay of testosterone administration.

of steroids in urine from individuals of different countries. One is that there is a considerable spread in values but one that is unrelated to race and "typical regional diets," at least based on the small sample studied. The lowest and highest $\delta^{13}\text{C}^0/00$ among this group differed by 4 units (-24 to -28); however, both these sets of values came from Caucasians. The remaining samples from different nationalities and ethnic groups fell within this range, a particularly important finding with respect to the current study, because it suggests that the results obtained following testosterone administration are universally applicable.

Diet of individuals must have the greatest part to play in the establishment of an individual's $\delta^{13}\text{C}$ value. Because all food originates as plant life (including animal protein), it was interesting to research what is known of $\delta^{13}\text{C}^0/00$ values for dietary plants. Smith and Epstein³ published the ^{13}C content of 104 plants, but relatively few were commonly used foodstuffs. A few were high $^{13}\text{C}/^{12}\text{C}$ plants (corn, sugar cane, grain, and sorghum) averaging around $\delta^{13}\text{C}^0/00$ -14 , but most were categorized as a separate group of low $\delta^{13}\text{C}^0/00$ species having values between -23 and -30 . These include dietary oil precursors (olive, sunflower, and castor) and various vegetables (wheat, grass, bamboo, peas, squash, radish, beets, and citrus fruit). Because typical worldwide diets of human and domestic animals use mostly low $\delta^{13}\text{C}^0/00$ plants, we would anticipate that $\delta^{13}\text{C}$ values for excreted steroids would fall in the -23 to -28 range, as found. The $\delta^{13}\text{C}^0/00$ value of an individual plant species does not vary significantly dependent on geographic location,³ and variation only manifests itself in plants grown in urban areas where CO_2 from fossil fuels increases the ^{12}C content slightly. This clearly does not markedly affect agricultural foodstuffs. For the purposes of this assay technique, it is fortuitous that synthetic testosterone is obviously derived from a very low $\delta^{13}\text{C}^0/00$ plant species, otherwise no distinction would be possible between endogenous and exogenous compound.

Practicality of methodology for use in doping control

We compared our $\delta^{13}\text{C}^0/00$ values for androstanediol with those of Aguilera et al., who used similar methodologies but different instrumentation.⁵ They studied individuals of different nationality and ethnicity than ours. For the purposes of this comparison, we averaged our values for 5α - and 5β -androstanediol, because their values were based on measurement of the combination. For baseline samples, we obtained an averaged $\delta^{13}\text{C}^0/00$ of -26.87 , which agreed excellently with Aguilera's⁵ value of -26.52 . For androstanediols measured during testosterone administration, they obtained an average value of -32.44 ; whereas, our value (the mean of duplicates of the lowest values for each individual) was -30.21 . Although our minimum value is not as low as that of Aguilera, it was still well below the baseline level, so it could be used for proving testosterone abuse. The difference in results between the laboratories could be attributed to their use of a testosterone with lower $\delta^{13}\text{C}^0/00$ (its origin was not reported) or unequal calibration of the different instruments used.

Our methodology is multistep, albeit built around low-

technology procedures. Within the technique, there is only one chromatographic separation, and that was designed to produce a broad fraction rather than the isolation of individual steroids. The key to the method is separate isolation of nonketonic steroids, a procedure that in one extraction step removes 75% of unwanted steroids from urine. A second classical procedure, the oxidative removal of side chains from 17-hydroxypregnane steroids removes many of the remaining complex steroids from the mixture, resulting in a cleaner chromatogram, although in the future, we may simplify the method by discontinuing this procedure if satisfactory results can be obtained. Typically, without using any automation in wet chemistry procedures, a batch of samples requires 1 day of technician time to extract and derivatize. The mass spectrometry was automated, and later 20 minutes were required for each run. The maximum number of samples that could be analyzed per 24 h was, therefore, 72.

The length of time that the 250-mg testosterone enanthate dose (equivalent to 180-mg free testosterone) clearly manifested itself in decreased $\delta^{13}\text{C}^0/00$ value was 8–10 days. This compares well with other parameters studied on this cohort. For example, plasma testosterone was measured, and from being grossly elevated in the first few days after administration, it returned to normal by the 8th day, although the steroid itself may well be largely of exogenous origin on this occasion.¹¹ In addition, we report the T/E ratios that are particularly interesting, because essentially only three out of the eight individuals achieve values >6 on more than 1 day, showing a high rate of false negatives. This may not be a universal finding and may well be related to the race (Asian) of the studied individuals. However, it once again emphasizes the importance of developing alternate methodology for proving testosterone misuse. The elevated T/E ratios (although most are <6) fall significantly by the 11th day of the study in all subjects.

We believe that our method based on androstanediol measurement has the needed sensitivity for use in doping control. Although we analyzed all samples in duplicate and plotted the graphs from their averages, individual analyses were equally informative (Figure 4B, C). We would have no hesitation in confirming testosterone administration based on a single measurement. We have been able to get up to five analyses of a single sample using splitless gas chromatographic injection. This represents an equivalent of 5 mL urine for each analysis, which meets sample availability in doping control. Use of a solid injection device for GC, such as glass minivials in a carousel,¹² could improve this sensitivity greatly, because the total sample could be volatilized and passed into the GC/IRMS instrument. Testing of a urine volume of 2 mL by our procedure and the Micromass IRMS instrument would be realistic. Our method has two obvious advantages over that of Aguilera et al.⁵ One is that the two androstanediols are determined separately, so even if one peak was too small or showed evidence of contamination, the second peak could give the required value. A second advantage is that all analytes are measured in the same chromatogram; whereas, in Aguilera et al.'s study, at least two separate GC/C/IRMS analyses are required to measure the isotope ratio in the androstanediols and their

ERC cholesterol acetate. However, in fairness, they did have a more difficult assay through the inclusion of testosterone itself among the analytes.

Manipulating the result of a drug test to give a "negative" result following testosterone administration would be difficult. Although the AD/PD ratio could be normalized by taking commercial pregnanediol (Sigma, $\delta^{13}\text{C}^0/00$ value -32.12) the low "absolute" value for pregnanediol would give the situation away. Similarly, commercial androstane-diols also have very low $\delta^{13}\text{C}^0/00$ values (Sigma -34.00) so self-administration of these compounds would not increase the δ values of testosterone derived metabolites. Probably the only way to fool such a test would be to alter the diet drastically over a long period of time through exclusively ingesting foodstuffs with $\delta^{13}\text{C}^0/00$ values below -29 . False positives could be obtained by ingestion of nonproscribed steroids such as the now commonly used dehydroepiandrosterone (DHEA), which also partially metabolizes to androstane-diols. However, whether testosterone or DHEA was being administered could easily be determined from marked differences in the total urinary steroid profile.

Acknowledgments

These studies were made possible through the generous support of the U.S. Olympic Committee and its representatives Dr. Wade Exum and Dr. James Betts. Financial support was also provided by Children's Hospital Oakland Research Institute. The authors thank Dr. Victor Rogozkin (St. Petersburg), Dr. Lubos Stárka (Prague), and Drs. Xavier de la Torre and Jordi Segura (Barcelona) for donating synthetic testosterone standards. Thanks are also given to individuals from different countries who provided urine samples for analysis. These studies could not have been carried out without the continual mass spectrometric maintenance and training undertaken by Ms Esther Roitman.

Review

Applied gas chromatography coupled to isotope ratio mass spectrometry

W. Meier-Augenstein*

Department of Anatomy and Physiology, University of Dundee, Small's Wynd, Dundee DD1 4HN, Scotland, UK

Abstract

Compound-specific isotope analysis (CSIA) by isotope ratio mass spectrometry (IRMS) following on-line combustion (C) of compounds separated by gas chromatography (GC) is a relatively young analytical method. Due to its ability to measure isotope distribution at natural abundance level with great accuracy and high precision, GC–C–IRMS has increasingly become the method of choice in authenticity control of foodstuffs and determination of origin in archaeology, geochemistry, and environmental chemistry. In combination with stable isotope labelled compounds, GC–C–IRMS is also used more and more in biochemical and biomedical application as it offers a reliable and risk-free alternative to the use of radioactive tracers. The literature on these topics is reviewed from the advent of commercial GC–C–IRMS systems in 1990 up to the beginning of 1998. Demands on sample preparation and quality of GC separation for GC–C–IRMS are discussed also. © 1999 Elsevier Science B.V. All rights reserved.

1. Introduction

During the 14 years that followed the first publications reporting the coupling of gas chromatography (GC) to on-line combustion of GC separated compounds to yield CO_2 and N_2 for isotope ratio analysis by a single collector mass spectrometer [1,2], hardly any work was published that made use of this new technique. Drawing on this work, in 1984, Barrie et al. [3] coupled a dual collector mass spectrometer to a GC via an on-line combustion interface, thus permitting continuous recording of $(m+1)/m$ isotope ratios by detecting two successive masses at the same time. Their instrument was the first genuine GC-combustion interfaced-isotope ratio mass spectrometry (GC-C-IRMS) system and produced isotope ratios that were an order of magnitude more precise than obtained from an optimised single collector instrument.

However, it was not until 1990 that GC-C-IRMS instruments became commercially available. Since then, GC-C-IRMS instrumentation has experienced several advances and its application has increased to such an extent that it "could almost be considered a conventional technique" [4].

Tom Brenna of Cornell University's Division of Nutritional Sciences, once said "IRMS is probably the first form of analytical mass spectrometry" (see Ref. [166]). IRMS is certainly a very sensitive detector, able to yield highly precise measurements of isotope ratios with a standard deviation in the range of four to six significant figures. When coupled to a GC system, it enables the analyst to conduct

highly precise compound-specific isotope analysis (CSIA), especially at natural isotopic abundance level. High-precision CSIA at natural abundance level can provide information on biogenetic relation and origin of a given organic compound. Compared with authentic reference data, subtle differences in the isotopic abundance of ^2H , ^{13}C , ^{15}N , or ^{18}O can thus help uncover adulteration of foodstuff or drug abuse in sports to name but a few.

There is also an increasing interest in the application of high-precision CSIA in tracer studies. One area of application is concerned with quantitative studies of biochemical processes such as assimilation/incorporation of nutrients, turnover rates of biologically important molecules, and quantitation of protein synthesis. The other area aims to improve detection limits of bio-organic molecules by using labelled precursor compounds at high enrichment levels.

In either case, high-resolution capillary gas chromatography (HRcGC) is a prerequisite for high-precision CSIA by on-line IRMS. Peak overlap and peak distortion have a detrimental effect on both accuracy and precision of isotope ratio measurements. It is therefore not surprising that scientists working on high-precision CSIA by on-line IRMS invariably employ HRcGC methods.

It is the aim of this article to provide a review over the current spectrum of applied GC-C-IRMS in conjunction with the HRcGC aspects involved. To illustrate as to why the two are inextricably linked, the first section of this review will deal with the characteristics of IRMS and GC-C-IRMS.

2. Principles of IRMS and GC–C–IRMS

2.1. IRMS

In order to understand why HRcGC is quintessential for high precision CSIA one needs to appreciate exactly how IRMS works. In contrast to so-called organic mass spectrometers (MS) that yield structural information by scanning a mass range (typically over several hundred amu) for characteristic fragment ions, IRMS instruments achieve highly precise measurement of isotopic abundance at the expense of the flexibility of scanning MS.

For isotope ratio measurement, the analyte must be converted into a simple gas, isotopically representative of the original sample, before entering the ion source of an IRMS. Continuous flow isotope ratio measurements of $^2\text{H}/^1\text{H}$, $^{15}\text{N}/^{14}\text{N}$, $^{13}\text{C}/^{12}\text{C}$, $^{18}\text{O}/^{16}\text{O}$ and $^{34}\text{S}/^{32}\text{S}$ are performed on gases of H_2 , N_2 , CO_2 , CO and SO_2 , respectively, with ^{13}C abundance measurements accounting for almost 70% of all gas isotope ratio analyses made. One also has to bear in mind that IRMS, in fact, determines the difference in isotope ratio with great precision and accuracy rather than the absolute isotope ratio. IRMS measurements yield the information of isotopic abundance of the analyte gas relative to the measured isotope ratio of a standard or reference gas. This is done to compensate for mass discriminating effects that may fluctuate with time and from instrument to instrument. In dual-inlet IRMS systems, sample gas and standard gas are introduced into two separate gas reservoirs (bellows) and a changeover valve array is used to toggle bellow effluents between the ion source and a waste line, thus maintaining constant viscous flow.

To achieve accurate and highly precise measurement of isotope ratios, obviously great care must be taken to ensure that no part of the analyte data is lost. In the case of CO_2 , the data comprise three ion traces for the different isotopomers $^{12}\text{C}^{16}\text{O}_2$, $^{13}\text{C}^{16}\text{O}_2$ and $^{12}\text{C}^{18}\text{O}^{16}\text{O}$ with their corresponding masses at m/z 44, 45 and 46, respectively. The three ion beams are registered simultaneously by a multiple Faraday cup (FC) arrangement with a dedicated FC for each isotopomer. The resulting ion currents are continuously monitored, subsequently digitised and trans-

ferred to the host computer. Here, the peak area for each isotopomer is integrated quantitatively and the corresponding ratios are calculated.

In both application areas of IRMS (low level enrichment and natural abundance work), small variations in very small amounts of the heavier isotope are detected in the presence of large amounts of the lighter isotope. The abundance A_s of the heavier isotope n_2 in a sample s , given in at.%, is defined as:

$$A_s = R_s / (1 + R_s) \times 100 \text{ (at.\%)} \quad (1)$$

where R_s is the ratio n_2/n_1 of the two isotopes for the sample. The enrichment of an isotope in a sample as compared to a standard value (A_{std}) is given in at.% excess (APE):

$$\text{APE} = A_s - A_{\text{std}} \quad (2)$$

Since the small variations of the heavier isotope habitually measured by IRMS are of the order of 0.001–0.05 at.%, the δ -notation in units of per mil (‰) has been adopted to report changes in isotopic abundance as a per mil deviation compared to a designated isotopic standard:

$$\delta_s = (R_s/R_{\text{std}} - 1) \times 1000 \text{ (‰)} \quad (3)$$

where R_s is the measured isotope ratio for the sample and R_{std} is the measured isotope ratio for the standard.

2.2. GC–C–IRMS

From the above it is obvious that a GC cannot be directly coupled to an IRMS. The need for sample conversion into simple gases has prompted the design of a combustion interface where the GC effluent is fed into a combustion reactor (Fig. 1). This reactor, either a quartz glass or ceramic tube, is filled with CuO/Pt or $\text{CuO}/\text{NiO}/\text{Pt}$ and maintained at a temperature of approximately 820 or 940°C, respectively [5,6]. The influence of combustion tube packing on analytical performance of GC–C–IRMS has been reported by Eakin et al. [7]. To remove water vapour generated during combustion, a water trap is required. Most instrument manufacturers employ a Nafion tube for this purpose. Nafion is a fluorinated polymer that acts as a semi-permeable

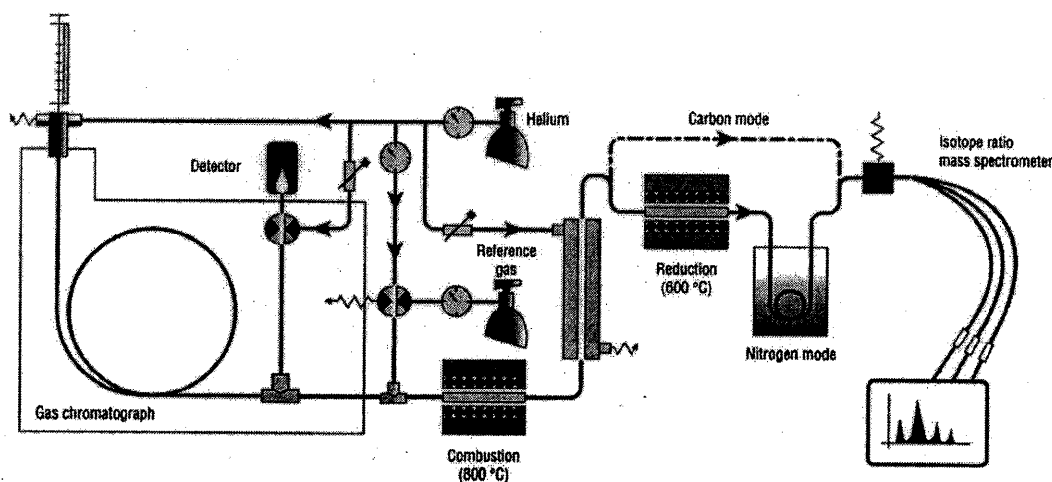

Fig. 1. Set-up of an isotope ratio mass spectrometer coupled to a gas chromatograph via a combustion interface to measure $^{13}\text{C}/^{12}\text{C}$ (carbon mode) or $^{15}\text{N}/^{14}\text{N}$ ratios (nitrogen mode). This schematic shows the reference gas set-up used for automated internal isotopic calibration [24].

membrane through which water passes freely while all the other combustion products are retained in the carrier gas stream. Quantitative water removal prior to admitting the combustion gases into the ion source is essential because any water residue would lead to protonation of CO_2 to produce HCO_2^+ , which interferes with analysis of $^{13}\text{CO}_2$ (isobaric interference). Very recently, a detailed study of this effect has been reported by Lecktrone and Hayes [8].

In dual-inlet systems, the analyte gas comes from a reservoir and only travels a short distance prior to entering the ion source. For this reason, the gas pulses result in rectangularly shaped signals. In contrast, in continuous flow IRMS (CF-IRMS) systems used for gas isotope analysis on-line gas purification steps and overall interface length lead to Gaussian-shaped signals. This is evidently even more pronounced in GC-C-IRMS systems, where analyte peaks eluting from the GC column are fed into an on-line microchemical reactor to produce, e.g., CO_2 peaks. However, due to the chromatographic isotope effect [9–11] the m/z 45 signal ($^{13}\text{CO}_2$) precedes the m/z 44 signal ($^{12}\text{CO}_2$) by 150 ms on average (Fig. 2) [5], an effect not observed in ordinary CF-IRMS systems. This time displacement depends on the nature of the compound and on chromatographic parameters such as polarity of the stationary phase, column temperature and carrier gas flow [12]. There-

fore, loss of peak data due to unsuitably set time windows for peak detection and, hence, partial peak integration will severely compromise the quality of the isotope ratio measurement by GC-C-IRMS, as will traces of peak data from another sample compound due to close proximity resulting in peak overlap with the sample peak to be analysed. Due to the fact that isotope ratios cannot be determined accurately from the partial examination of a GC peak, HRcGC resulting in true baseline separation for adjacent peaks is of paramount importance for high-precision CSIA.

It should be noted, that the chromatographic isotope effect is not caused by a vapour pressure effect but is the result of different solute/stationary phase interactions that are dominated by Van der Waals dispersion forces leading to an earlier elution of the heavier isotopomer [11]. This difference in chromatographic solute/stationary phase interaction is caused by lower molar volumes of the labelled, and thus heavier, compounds. The reason for the decrease in molar volume is the increased bond strength and thus shortened bond length between $^{13}\text{C}-\text{H}$ and, to a lesser degree, $^{12}\text{C}-^{13}\text{C}$, and $^{12}\text{C}-\text{H}$ and $^{12}\text{C}-^{12}\text{C}$, respectively. If the chromatographic isotope effect would indeed be the result of a vapour pressure effect, one would expect the lighter isotope species of a given compound to elute more rapidly

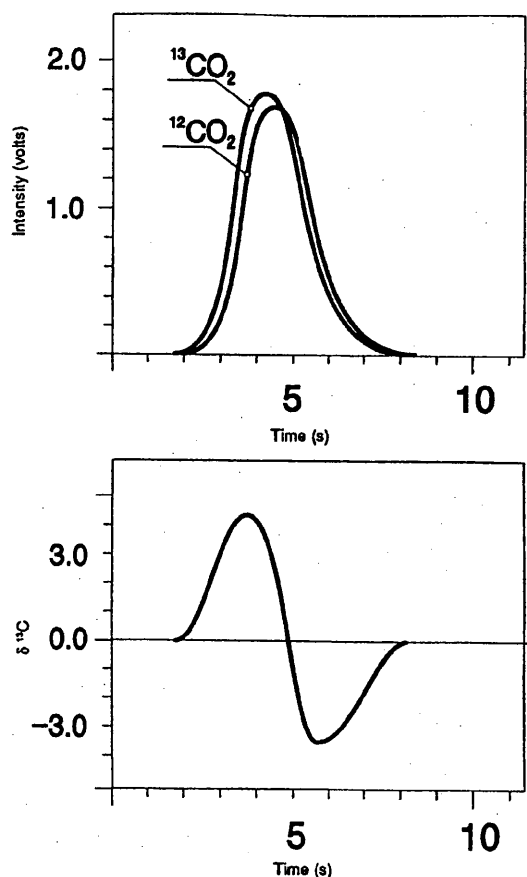

Fig. 2. Illustration of the time displacement between $^{13}\text{CO}_2$ and $^{12}\text{CO}_2$ that causes the S-shaped 45/44 ratio signal [5]. From Ref. [5], ©Intercept 1990.

from the column because of its higher vapour pressure and, hence, lower boiling point as compared to the heavier isotope species.

Although baseline separated peaks should be the ultimate goal in GC–C–IRMS, there is many an application where overlapping peaks simply cannot be avoided. In addition, CO_2 and N_2 disperse more freely within the carrier gas stream than their parent organic compounds resulting in overlapping CO_2 peaks for barely baseline resolved GC peaks. To extract the valuable information obscured by such peak overlaps, Goodman and Brenna [13,14] suggested software algorithms for improved data processing. These algorithms were based on curve fitting rather than the summation (the industrial

standard) using combinations of exponentially modified Gaussian (*E*) and Harhoff/Van-der-Linde (*H*) functions and were tested on up to 70% valley peak overlap. When the adjacent peaks were of equal abundance (leading peak:trailing peak, 1:1) combinations of HE and HH appeared to provide the best recovery of isotope ratios. In the case of unequal abundance in favour of the leading peak (10:1), the HH combination gave the best accuracy. When the abundance was reversed (1:10), the EH combination provided the best accuracy but only for peak overlap up to 40% valley. Despite these encouraging results, curve-fitting algorithms for restoring lost accuracy have not been incorporated into any commercial IRMS data reduction software by IRMS manufacturers. It could be argued that the potential of curve-fitting algorithms was only demonstrated on two compounds, methyl tridecanoate and butylated hydroxytoluene, which were of almost identical carbon isotope ratios and that any curve-fitting software should also be able to extract accurate and precise isotope ratios of two overlapping compound peaks with different carbon isotope ratios. However, any progress in this direction needs to be aided by full evaluation of new algorithms for routine use (under 'real life conditions'), thus requiring wide user access to such algorithms which in turn depends on the support from IRMS manufacturers.

2.2.1. Sample preparation

To achieve high-precision CSIA by GC–C–IRMS the following points must be considered:

- (1) Every step of the sample preparation protocol (collection, work up, derivatization) must be scrutinised for potential mass discriminatory effects to avoid isotopic fractionation of the target compounds.
- (2) If the potential of isotopic fractionation cannot be ruled out conclusively, an internal standard, of a similar chemical nature (but not requiring derivatization) and of known isotopic composition, should be added to the sample prior to sample preparation.
- (3) Signal size and isotopic composition of the standard(s) must match those of the analyte(s) [15].
- (4) The potential of all GC parameters (polarity of stationary phase, carrier gas management, temperature programme) and techniques should be exploited to their fullest to achieve HRcGC.

2.2.1.1. Derivatization

Despite their importance for high-precision CSIA, dedicated studies addressing issues of sample preparation are few and far between. Schumacher et al. compared different sample preparation methods for isotopic analysis of volatile organic compounds (VOCs) from strawberries [16]. Khalfallah et al. reported a correction method to compensate for ^{13}C tracer dilution by carbon added during derivatization [17], and a carbon balance equation was described by Demmelmair and Schmidt to calculate $\delta^{13}\text{C}$ values of free amino acids from $\delta^{13}\text{C}$ values of their derivatives at natural abundance level [18]. Kinetic isotope effects associated with derivatization reactions and resulting theoretical considerations for calculating $\delta^{13}\text{C}$ values have been discussed by Rieley [19].

Of course, one way of avoiding the problems with derivatization is not to derivatize the sample at all. This approach involves the use of moderately polar to polar stationary phases and high-temperature GC. However, not all polar compounds are amenable to these techniques (e.g., amino acids) and high-temperature capability of polar stationary phases is limited even when oxygen free helium is used as carrier gas.

In addition to changes in ^{13}C isotopic signature by derivatization, its effects on GC separation and sample conversion into CO_2 and N_2 have to be considered. Derivatization by silylation might hamper GC separation as the apolar nature of trimethylsilyl (TMS) and *tert*-butyldimethylsilyl (tBDMS) derivatives can obscure compound characteristics that could otherwise be chromatographically exploited. Furthermore, an excessive carbon load introduced by derivatization might result in incomplete combustion thus compromising accurate isotopic analysis. For reasons of non-quantitative sample conversion, the use of trifluoroacetates (TFA) or heptafluorobutyrate (HFB) is not advisable as fluorine forms extremely stable fluorides with Cu and Ni, thus irreversibly reducing combustion efficacy of the CuO/NiO system. In addition, fluorine poisons the combustion catalyst platinum. Experiments with *N*-TFA, *O*-propylates of alanine and leucine have shown that only 50% of the expected CO_2 yield was produced [20].

2.2.2. Isotopic calibration

For reasons mentioned before, it is not possible in GC–C–IRMS to calibrate target compounds against a standard of known isotopic composition, introducing the standard in exactly the same way as the analyte. There are only three feasible means of introducing a standard: (a) addition of reference compounds to the sample, (b) introduction of reference gas pulses to the carrier gas stream, or (c) introduction of reference gas pulses directly into the ion source.

Caimi et al. comprehensively listed all the desirable properties internal reference compounds should possess: (1) high chemical stability; (2) conveniently available in high purity; (3) readily soluble in high-purity solvents; (4) low vapour pressure at room temperature and atmospheric pressure; (5) environmentally rare; (6) ideally useful for GC and liquid chromatography (LC) techniques; and (7) sufficiently different chromatographic characteristics to avoid partial or complete co-elution with sample analytes [21].

The results of an extensive study into methods of isotopic calibration by Merritt et al. emphasised these demands [22]. Comparing the use of internal reference compounds with the introduction of reference gas pulses directly in the ion source of the IRMS, Merritt et al. found an offset of $>2\%$ between the two methods in the case of incomplete combustion and other systematic errors affecting only the analytes. These systematic errors affected both the analytes and the co-injected reference compounds but were not reflected by the external reference gas pulses. Similar observations were made by other groups interested in isotopic calibration [12,21,23]. In the absence of such systematic errors, Merritt et al. found that both methods of isotopic calibration gave consistent results as long as multiple reference peaks were used to permit drift correction. Only one reference peak for isotopic calibration, albeit from an internal reference compound, is not enough to compensate for the influence of GC parameters, such as analyte/stationary phase interaction, column temperature on measured isotope ratios [12].

Within the GC–C–IRMS system, seven potential sources for mass discrimination and, hence, sys-

tematic errors can be identified: (1) isotopic fractionation during sample injection (which can be overcome by on-column or time programmed splitless injection); (2) chromatographic isotope effect; (3) chromatographic peak distortion (leading and trailing peak tail); (4) combustion process; (5) peak distortion of N_2/CO_2 gas peak during passage of the combustion interface; (6) changing flow conditions at the open split prior to the IRMS; and (7) the IRMS itself. Obviously, the external reference gas pulses only compensate for item (7), whereas internal reference compounds reflect all of the aforementioned. Recently, a method for isotopic calibration was reported that, provided a combustible gas was used, could reflect the systematic errors caused by items (4–7) [24]. This method combines the convenience and practicability of external reference gas calibration with the advantage of reflecting the majority of physical influences to which analytes are subjected in a GC–C–IRMS system.

2.2.3. HRcGC

As pointed out earlier, baseline separated gas chromatographic peaks are the basis for high-precision CSIA. To achieve this goal, in the first instance, basic gas chromatographic rules must be observed: (1) the polarity of the stationary phase should meet the polarity of the analytes; (2) column head pressure and, hence, carrier gas velocity, should be set to suit column diameter; and (3) temperature gradients should be chosen to exploit the maximum of the

column length (the longer the column, the slower the temperature rise per minute; cf. Table 1) [25].

Further to these principles, HRcGC techniques such as multi-dimensional capillary GC (MDcGC), enantio-selective GC, porous layer open tubular (PLOT) column GC for analysis of VOCs and high-temperature capillary GC (HTcGC) are powerful tools for high-precision CSIA when used in combination with GC–C–IRMS. Nitz et al. were the first to report the advantages of using MDcGC in GC–C–IRMS [26]. MDcGC is now, often in combination with enantioselective GC, almost exclusively used in authenticity control of flavours and fragrances by CSIA [27,28]. In a similar fashion, HTcGC is strongly associated with CSIA of steroids and long-chain fatty acids (e.g., Ref. [29]).

Regrettably, the achievements of HRcGC in terms of well-defined peak shape and baseline separation are likely to be impaired during combustion and the subsequent passage through the interface. Changes in tubing diameter and frequent use of unions to connect the various parts of tubing lead to a loss in peak definition (peak broadening; peak distortion) and even to partial peak overlap, all of which have a detrimental effect on accuracy and precision of isotope ratio measurement [12]. Very recently, Goodman reported a single-capillary interface design (SCID) which he developed to overcome these problems [30]. As the name suggests, a single capillary was used to connect the GC column to the open-split in front of the IRMS. This capillary was threaded through a furnace and accommodated two

Table 1

Recommended values for carrier gas velocity and temperature gradient according to column length when using helium as carrier gas^a

| Column length (m) | Elution of methane (s) ^b | Temperature gradient (°C/min) |
|-------------------|-------------------------------------|-------------------------------|
| 10 | 35 | 2.5 |
| 15 | 53 | 1.65 |
| 20 | 70 | 1.25 |
| 25 | 88 | 1.05 |
| 30 | 105 | 0.84 |
| 40 | 140 | 0.63 |
| 50 | 175 | 0.5 |

^bSet GC oven temperature to 30°C. Set split ratio to about 1:30, inject a few μ l of natural gas (or lighter gas) and measure elution time of the first peak (FID signal). Adjust column head pressure to match recommended elution time.

CuO wires positioned thus as to coincide with the furnace dimensions. So far, this design has been tested for ^{13}C isotopic abundance analysis of *n*-alkanes.

3. High-precision CSIA of ^{13}C isotopic abundance

3.1. GC–C–IRMS at natural abundance level

High-precision CSIA of ^{13}C isotopic abundance at both natural abundance (NA) and low enrichment

level can yield measurements of $\delta^{13}\text{C}$ values with a precision of 0.3‰ on average. Thanks to this high precision, even small changes in ^{13}C isotopic abundance of 1‰ can be reliably detected. For this reason GC–C–IRMS has become the method of choice to determine the origin of a given organic compound by measuring its characteristic isotope ‘finger print’.

In contrast to the generally held opinion, the natural abundance of stable isotopes is not a fixed constant but displays a considerable, yet subtle, degree of variation. The variation on the natural abundance of ^{13}C can be as high as 0.1 at.% (Fig. 3). This wide range reflects the varying degree of mass

Fig. 3. Some typical examples of natural $\delta^{13}\text{C}$ values grouped according to origin along the scale of ^{13}C natural abundance.

discrimination associated with the different pathways of carbon assimilation and fixation. To give an example, in terms of ^{13}C isotopic abundance, beet sugar is not the same as cane sugar. In sugar beet CO_2 fixation results in the formation of a C_3 body, 3-phosphoglycerate (3-PGA). This pathway of CO_2 fixation is known as the Calvin cycle. Plants using the 3-PGA pathway for CO_2 fixation are commonly called C_3 plants. However, some plants, of which sugar cane is one, make use of a different pathway. Here, CO_2 fixation yields a C_4 -dicarboxylic acid, oxalo acetate, hence the term C_4 plants (the C_4 -dicarboxylic acid pathway is also known as the Hatch–Slack cycle). The products of these two pathways are characterised by their different ^{13}C abundance. Glucose derived from C_3 plants has a $\delta^{13}\text{C}$ value of about -25‰ , whereas glucose derived from C_4 plants exhibits a more positive $\delta^{13}\text{C}$ value of about -11‰ indicating a mass discriminatory bias towards $^{13}\text{CO}_2$ of the Hatch–Slack cycle.

Differences in $\delta^{13}\text{C}$ values were reported for total leaf tissue, total surface lipid extracts, and individual n -alkanes isolated from plants utilising either C_3 , C_4 , and crassulacean acid metabolism (CAM) pathways for carbon fixation [31,32]. The average $\delta^{13}\text{C}$ values obtained from C_3 plant material were between 10 and 15‰ lower compared to the corresponding $\delta^{13}\text{C}$ values obtained from C_4 and CAM plant material. Measurement of the isotopic abundance of ^{13}C for lutein isolated from marigold (C_3) and maize (C_4) yielded -29.90 ± 0.20 and $-19.77 \pm 0.27\text{‰}$, respectively, showing a similar difference of $>10\text{‰}$ between the two photosynthetic pathways [33].

Although the vast majority of plants belong the C_3 group ($>300\,000$) with bulk $\delta^{13}\text{C}$ values of $<-24\text{‰}$, differences in the rate of photosynthesis (mainly caused by differences in climate and geographical location) and in enzyme kinetics of biochemical pathways result in subtle variation of $^{13}\text{C}/^{12}\text{C}$ ratios that can be detected by GC–C–IRMS. Lockheart et al. were able to detect inter- and intra-specific differences in $\delta^{13}\text{C}$ values for n -alkanes and alcohols in sun and shade leaves from oak and beech ranging from 0.7 to 3.0‰ [34]. These subtle differences in $\delta^{13}\text{C}$ values can be used to determine origin of an organic compound and, thus, the authenticity of a sample.

3.1.1. Authenticity

3.1.1.1. Flavours and fragrances

Bernreuther et al. measured $^{13}\text{C}/^{12}\text{C}$ isotope ratios of natural and nature-identical γ -decalactone and reported significant differences in $\delta^{13}\text{C}$ values that were source dependent although all plants belonged to the C_3 group [35]. For natural γ -decalactone from stone fruit (apricot and peach) they found $\delta^{13}\text{C}$ values ranging from -38.0 to -40.8‰ , respectively, that were significantly different from $\delta^{13}\text{C}$ values of γ -decalactone extracted from soft fruit (strawberry) which were -29.2‰ on average. In contrast, $\delta^{13}\text{C}$ values of artificial (nature-identical) γ -decalactone ranged from -24.4 to -26.9‰ , whereas γ -decalactone of biotechnological origin showed $\delta^{13}\text{C}$ values of -30.8‰ on average.

In an independent study, Mosandl et al. demonstrated the additional advantage to be gained from enantioselective GC–C–IRMS on samples of synthetic γ -decalactone (racemate RAC; 4R:4S = 50:50), γ -decalactone of biotechnological origin (BIO; 4R $> 99\%$ ee), and a mixture of both (BIO: RAC = 60:40) [36]. They reported for the enantiomerically pure (4R)- γ -decalactone of biotechnological origin a $\delta^{13}\text{C}$ value of $-30.12 \pm 0.14\text{‰}$ which is in good agreement with the $\delta^{13}\text{C}$ values measured by Bernreuther et al. The separated enantiomers of the nature-identical product showed, as could be expected, identical $\delta^{13}\text{C}$ values within the observed standard deviation (4R, $-28.32 \pm 0.36\text{‰}$; 4S, $-28.18 \pm 0.39\text{‰}$). Mixing 60% of BIO with 40% of RAC yielded an enantiomeric distribution of 4R:4S = 80:20, with 75% of the 4R-configured γ -decalactone being of biotechnological origin. The measured $\delta^{13}\text{C}$ value of the 4R enantiomer in this mixture was $-29.62 \pm 0.33\text{‰}$ which was in good agreement with the theoretically expected value of -29.67‰ . The $\delta^{13}\text{C}$ value of the 4S enantiomer in this mixture was of course the same as for the 4S enantiomer in the pure synthetic sample ($-28.08 \pm 1.30\text{‰}$).

This early work suggested that two phenomena of biosynthetic pathways, enantioselectivity and mass discrimination (kinetic isotope effects), might serve as compound-specific parameters to establish origin and, hence, to control authenticity of natural flavours and fragrances. However, when focused on indi-

vidual compounds the application of stable isotope abundance measurement is only of limited use as most plants cultivated for human consumption are C_3 plants whose ^{13}C isotopic signatures partially overlap with those of synthetic compounds derived from fossil sources or those of compounds produced by biotechnological methods.

This problem was soon recognised and Mosandl's group suggested the use of genuine internal isotopic standards and formulated the following recommendations [37,38]:

- (1) the compound selected as internal isotopic standard should be a genuine characteristic compound of lesser sensorial relevance;

- (2) the compound must be available in the sample in sufficient amounts and must not be susceptible to mass discrimination during sample preparation;

- (3) the selected compound must be biogenetically related to the compounds under investigation;

- (4) chemical inertness of the compound during storage and/or technical processes is mandatory;

- (5) the compound selected as internal isotopic standard must not be a legally allowed additive.

The obvious advantage of using an internal standard, biogenetically related to characteristic sample compounds, is the elimination of variations in the $\delta^{13}C$ -signature resulting from, e.g., climate-dependent variations of the photosynthetic rate and the kinetic isotope effect associated with the CO_2 fixation step. Therefore, only the characteristic kinetic isotope effects caused by enzymatic reactions during secondary biogenetic pathways are investigated, and the resulting relative $\delta^{13}C$ values can be used as a sample-specific finger print (cf. Fig. 4).

Applying the aforementioned recommendations, Mosandl and co-workers, who have to be regarded as the leaders in the field of authenticity control, studied a wide range of commercially relevant flavours and fragrances and assessed authenticity of allegedly natural samples from commercial sources. The materials studied included lemon oil [37], balm oil [39], citronella oil [39], lemongrass oil [39], coriander oil [40], bergamot oil [41], orange oil [42], mandarin oil [43,44], peppermint oil [45], volatile components from strawberries [16] and apples [46] and α - as well as β -ionone from raspberries [47]. Using self-prepared authentic samples, sample-specific finger prints of six to eight biogenetically related compounds

were established based on $\delta^{13}C$ values relative to an internal standard (either limonene, γ -terpinene or neryl acetate). With the help of these finger prints, samples made up entirely of synthetic compounds and even samples containing mixtures of authentic (natural) material and synthetic compounds could be reliably identified. In cases where chiral compounds such as linalol occur naturally as enantiomeric mixtures (in coriander oil, $R:S=20:80$), enantioselective GC-C-IRMS could even detect non-authentic samples imitating the natural enantiomeric ratio by measuring the $\delta^{13}C$ values of each enantiomer [40,48].

3.1.1.2. Wine, fruit juice and honey

In the early days of GC-C-IRMS, detection of added sugar in fruit juice and wine was fairly simple as mainly cheap corn syrup (maize: C_4 plant) was predominantly used to boost sugar and/or ethanol content, respectively. Measuring $\delta^{13}C$ values of glucose or bulk carbon was sufficient to prove adulteration. However, addition of small amounts of C_4 plant sugars ($\leq 10\%$) to C_3 plant products such as wine, fruit juice and honey, or the addition of sugars from other C_3 plants (sugar beet; concentrated and decaffeinated grape juice) could no longer be detected by these measurements [49]. Schmidt and co-workers studied several methods based on high-precision CSIA to determine authenticity of wine, fruit juices and honey, and to prove fraudulent addition of sugars and even vitamin C from other sources. Their research revealed that in authentic fruit juices biogenetically related compounds such as L-ascorbic acid [50,51], L-malic acid [52] and L-tartaric acid [51] showed $\delta^{13}C$ values strongly correlating with those of their corresponding sugars. For instance, the $\delta^{13}C$ value of L-ascorbic acid is +4.8‰ higher than that of its precursor glucose. This enrichment is mainly located in the C-1 position of L-ascorbic acid of authentic origin and the result of plant-specific kinetic isotope effects during biosynthesis, whereas L-ascorbic acid of biotechnological origin preserves the ^{13}C pattern of glucose [51].

In glycerol originating from natural sources, Weber et al. found a ^{13}C depletion position specific for C-1 and they suggested this unique feature might be used as a means to test for illegal addition of synthetic glycerol to wines [53]. They also discov-

Fig. 4. $\delta^{13}\text{C}$ fingerprint of biogenetically related compounds in lemon oils of different geographical origin (top graph). The graph at the bottom shows the $\Delta\delta^{13}\text{C}$ fingerprint of the samples obtained when using neryl acetate (8) as internal isotopic standard [38]. From [38], ©Marcel Dekker, 1995.

ered a constant $\Delta\delta^{13}\text{C}$ correlation between ethanol and citric acid (+2.4‰) in addition to the known $\Delta\delta^{13}\text{C}$ correlation between fermented sugar and ethanol (−1.7‰) [54]. Dennis et al. suggested the use of $\delta^{13}\text{C}$ values of sorbitol as a further means for authenticity control of wines [55].

3.1.1.3. Vegetable oils

High-quality, single-source vegetable oils are another target for fraudulent adulteration, i.e., partial or total substitution of minor quality and, hence,

cheaper oils for the high quality product. In a blind study, Woodbury et al. were able to detect the adulteration of maize germ oil with oils of C_3 plant origin down to a level of 5% (w/w) [56]. They found the saturated 16:0 fatty acid in maize oil to be more depleted in ^{13}C than the corresponding unsaturated fatty acids 18:1 and 18:2. In addition, consistent differences were observed for $\delta^{13}\text{C}$ values of vegetable oils from different geographical regions. In a subsequent study, Woodbury et al. determined fatty acid composition and $\delta^{13}\text{C}$ values of the major fatty acids of more than 150 vegetable oils [57], thus

establishing a database that provides isotopic information for authenticity control of vegetable oils. Variability in $\delta^{13}\text{C}$ values could be related to geographical origin, year of harvest, and the particular variety of oil. Their findings suggest that ultimately $\delta^{13}\text{C}$ values of fatty acids are determined by a combination of environmental and genetic factors.

Kelly et al. investigated authenticity of single-seed vegetable oils of C_3 plant origin such as groundnut, palm, rape seed and sunflower oils [58]. They found that the $\delta^{13}\text{C}$ values for the authentic vegetable oil fatty acids fell within a narrow range of -27.6 to -32.1‰ . Employing canonical discriminant analysis, ^{13}C data from sunflower oil could be separated from other oils, exploiting small, yet significant, differences in $\delta^{13}\text{C}$ values within the oil varieties. To detect adulteration of olive oils, Angerosa et al. compared $\delta^{13}\text{C}$ values of the aliphatic alcoholic oil fractions and found those of the adulterant pomace oil to be significantly more negative than those of virgin and refined olive oils [59]. Furthermore, they studied isoprenoids and methylsterols isolated from each grade of olive oil and showed the better the olive oil grade, the more positive (i.e., less negative) the $\delta^{13}\text{C}$ values of these compounds became.

3.1.1.4. Drugs

Measuring ^{13}C isotopic abundance of heroin to trace the origin of heroin samples in narcotic drug abuse, showed some evidence of variation in $\delta^{13}\text{C}$ values of heroin depending on its geographical site of production [60]. A preliminary study to trace the origin of different batches of confiscated 3,4-(methyldioxy)methylamphetamine (MDMA, Ecstasy) tablets by GC–C–IRMS allowed the discrimination of four different groups of MDMA tablets based on variations in their NA $\delta^{13}\text{C}$ values [61]. The same study showed that further discrimination could be obtained when using $\delta^{15}\text{N}$ values of MDMA.

Prompted by the uncertainty associated with the $\text{T/E} > 6$ test that measures the ratio of testosterone (T) and epitestosterone (E) and the high public interest in alleged doping in athletes, several studies have been carried out to use metabolic pathway related ^{13}C isotope patterns to differentiate between endogenous human testosterone and exogenous testosterone [62]. In the human body, testosterone is

synthesised from cholesterol via dehydroepiandrosterone and is then further metabolised to androstenediol. The group around Aguilera et al. found that the averaged $\delta^{13}\text{C}$ values for endogenous 5α - and 5β -androstenediol dropped from -26.52‰ before synthetic testosterone administration (natural background or baseline value) to -32.44‰ during testosterone administration [63]. Independent work by Shackleton et al. obtained a similar baseline $\delta^{13}\text{C}$ value of -26.87‰ and a drop down to -30.21‰ on average for androstenediol samples after a bolus administration of 250 mg exogenous testosterone [64,65]. This drop of about -2‰ lasted for up to 10 days before $\delta^{13}\text{C}$ values of androstenediol returned to their former baseline value. They also reported a narrow range of -29.15 to -30.41‰ for five synthetic testosterone samples manufactured in five different countries. Based on the results reported by Aguilera et al. [63] and their own, Shackleton et al. suggested a conservative cut-off value of -29.0‰ for androstenediol to identify unambiguously testosterone abuse for up to 7 days after administration.

Hydrocortisone abuse in horse racing and other equine sports can be confirmed on the basis of significantly different ^{13}C isotope patterns between endogenous urinary hydrocortisone and synthetic material. This method, proposed by Aguilera et al., employs conversion of urinary hydrocortisone into its bismethylenedioxy derivative to improve its gas chromatographic properties [66].

3.1.2. Origin

3.1.2.1. Geochemistry

The desire to study ^{13}C isotope abundance of sedimentary hydrocarbons on a molecular level was one of the driving forces behind the development of GC–C–IRMS. Geochemists and archaeologists wanted to extract all possible information contained in fossil biomarkers such as sedimentary long-chain alcohols and sterols [67], triterpene-derived hydrocarbons [68], neutral monosaccharides [69], long-chain alkanes [70–74], alkanes and isoprenoids [75,76], polycyclic aromatic hydrocarbons (PAHs) [77], amino acids [78–80] and phenolic acids [81].

Freeman et al. measured hydrocarbons from sediments deposited in the Messel shale and found a wide spectrum of $\delta^{13}\text{C}$ values ranging from -20

down to -75% , thus proving the equally wide spectrum of origins [82]. The extreme negative values were thought to indicate the activity of methanotrophic bacteria, as $\delta^{13}\text{C}$ values of $<-45\%$ thus far had only been observed for methane but not for larger molecules. This and others studies [68,69,73,83] demonstrated that sedimentary organic compounds contain contributions of bacterial origin rather than being solely of plant origin. Using GC–C–IRMS to measure ^{13}C isotope abundance in hydrocarbons from sedimentary rocks across the Precambrian–Cambrian boundary, Logan et al. [84] were able to shed some light on the development of multicellular life during the so-called ‘Cambrian explosion’. Based on the isotopic data, they could show a transition from an environment dominated by sulphate-reducing bacteria to one dominated by photosynthetic organisms, thus transforming the hitherto anaerobic ocean into an aerobic ocean.

3.1.2.2. Archaeology

Measuring $^{13}\text{C}/^{12}\text{C}$ isotope ratios has become an increasingly important tool to glean information on prehistoric diet and lifestyle from organic residues preserved in archaeological artefacts. Employing both HTcGC–MS and HTcGC–C–IRMS to identify chemical structures and measure $\delta^{13}\text{C}$ values, respectively, Evershed et al. showed that lipid extracts (C_{25} – C_{33} alkanes and a C_{29} ketone, nonacosain-15-one) from organic residues found in archaeological potsheds were derived from *Brassica* species (wild-type cabbage) [85]. Later work on organic residues from archaeological pottery vessels found C_{31} , C_{33} and C_{35} ketones with $\delta^{13}\text{C}$ values that were up to 10% higher than those found for the C_{29} ketones from wild-type *Brassica* species. Based on HTcGC–MS and HTcGC–C–IRMS data, Evershed and co-workers formed the hypothesis that a precursor/product relationship may exist between C_{35} ketones and fatty acids, and corresponding triacylglycerols such as tripalmitin and tristearin from animal fats [86]. Studying pyrolysis reactions of acyl lipids and monitoring their products by HTcGC–MS and HTcGC–C–IRMS, they could confirm that C_{31} , C_{33} and C_{35} mid-chain ketones found in archaeological pottery vessels were indeed derived from a mixture of free fatty acids [87]. Comparing carbon number distributions of triacylglycerols and $\delta^{13}\text{C}$ values of

16:0 and 18:0 acyl moieties of lipid compounds from extracts of neolithic vessels with modern reference animal fats, Evershed et al. could identify animal fat residues found in vessels dated circa 4200 BP as being close to reference pig adipose fats, whereas residues found in vessels dated circa 4500 BP were closer to reference ruminant fat [88].

O'Donoghue et al. reported $\delta^{13}\text{C}$ values in the range of -25.4 to -29.2% for the principal fatty acids (16:0 to 24:1) of radish seed found in a 6th century AD storage vessel [89]. Composition and $\delta^{13}\text{C}$ values of fatty acids found in the ancient radish seeds matched closely those found in modern radish seeds.

Stott et al. measured $\delta^{13}\text{C}$ values of cholesterol and 3β -hydroxycholest-5-en-7-one from fossil whale bones [90] and archaeological human bones and teeth [91], and showed that their ^{13}C content could be used as an important new source of palaeodietary information. Another insight into prehistoric life was gleaned from the ^{13}C analysis of adsorbed lipids preserved in the fabric of Minoan lamps and conical cups. The $\delta^{13}\text{C}$ values together with HTcGC–MS profiles identified beeswax as the illuminant burned in prehistoric Aegean lamps rather than olive oil as hitherto supposed [92].

3.1.2.3. Environmental chemistry

Monitoring environmental and climate changes by measuring $\delta^{13}\text{C}$ values of atmospheric gases such as methane, carbon monoxide and carbon dioxide has traditionally been carried out using dual-inlet IRMS systems. Their measurements however, required time-consuming sample preparation of large sample volumes. The high abundance sensitivity of GC–C–IRMS together with the use of PLOT fused-silica capillary columns for routine GC analysis of highly volatile organic compounds (HVOCs) has now become the method of choice for scientists as air samples between $50\ \mu\text{l}$ and $5\ \text{ml}$ can be analysed on-line without any prior sample preparation [93–95].

High-precision CSIA by GC–C–IRMS is also used to determine origin and identify sources of oil spills and oil pollution [96–98], ocean-transported bitumen [99], characterisation of refractory wastes at heavy-oil contaminated sites [100,101] and to trace

the sources of PAHs in the environment [102–104]. Bird et al. used GC–C–IRMS to record the $\delta^{13}\text{C}$ values of individual biomarker compounds (*n*-alkanes) to assess vegetation changes [105], whereas Naraoka et al. measured differences in $\delta^{13}\text{C}$ values of long-chain fatty acids (C_{20} – C_{30}) that had been extracted from terrestrial and marine sediment [106].

3.2. Tracer studies

The high abundance sensitivity of GC–C–IRMS has also been increasingly exploited in metabolic studies investigating turnover, incorporation and synthesis processes *in vivo* that could previously only be investigated either with stable isotope tracers at high enrichment level using GC–MS, or not at all. The latter usually for reasons of excessive tracer dilution in the various metabolic pools and/or low incorporation rates. Although in these cases radioactive tracers can provide an alternative, their use is associated with certain risks which are nowadays regarded as unacceptable especially when dealing with members of the paediatric age group.

GC–C–IRMS proved to be a decisive tool in determining if and to what extent neonates and premature infants of very low birth weight could synthesise arachidonic acid, which is essential for their growing tissues, from dietary fatty acids. Demelmair et al. could show that in neonates fed on a phenylalanine-free diet, on average 23% of free plasma arachidonic acid on study day 4 originated from infantile linoleic acid conversion [107]. They determined ^{13}C content of linoleic acid and arachidonic acid in 0.25–0.5 ml serum before and for 4 days after the infants' diet contained corn oil. Baseline $\delta^{13}\text{C}$ values for linoleic acid and arachidonic acid were -31.5 ± 1.1 and $-30.1 \pm 1.2\text{‰}$, respectively; after 4 days, changes in $\delta^{13}\text{C}$ values over baseline were $+12.7 \pm 0.7$ and $+2.7 \pm 0.7\text{‰}$, respectively. Carnielli et al. added linoleic acid and linolenic acid, both ^{13}C -labelled, to the formula diet which was administered continuously for 48 h (birth weight, 1.17 ± 0.12 kg; gestational age, 28.4 ± 1.3 weeks) [108]. They could show that both tracers were rapidly incorporated into plasma phospholipids and that their metabolic products including arachidonic acid and docosahexaenoic acid became highly

enriched with ^{13}C . Incorporation of ^{13}C -octanoic acid into plasma triglycerides (10% of the enrichment of the diet), noticeably into myristic and palmitic acid, by very low-weight preterm infants was reported earlier by the same group [109].

A similar observation was made during a study with an entirely different objective. Using GC–C–IRMS, Koziat et al. could demonstrate that ethanol itself may be used as a substrate for lipogenesis, although only to a small extent [110]. They calculated that $<10\%$ of fatty acids contained in very-low-density lipoproteins (VLDL) triglycerides were derived from this pathway, with ethanol predominantly being incorporated into myristic and palmitic acid.

The majority of ^{13}C tracer studies published have dealt with various aspects of fatty acid biochemistry, such as metabolism of triglycerides [111,112], and transport and turnover of free saturated [113–115] and unsaturated fatty acids [116–120]. While studying the metabolism of ^{13}C -labelled polyunsaturated fatty acids by ^{13}C NMR, using GC–C–IRMS, Cunnane et al. found low levels of ^{13}C -labelled γ -linolenic acid in brain phospholipids of suckling rat pups that could not be detected by ^{13}C NMR [121].

Employing ^{13}C tracers at low levels of enrichment, reliable data were obtained in studies of the kinetics of glucose [122,123] and glycoprotein neutral sugars [124,125], cholesterol and lipoproteins [126], phosphatidylcholine [127], urea [128,129], branched-chain amino acid metabolism [130], measuring protein fractional synthetic rates [131] and protein synthesis in colorectal cancer cells [132,133]. Roscher et al. used L-rhamnose with two different levels of ^{13}C abundance in parallel experiments to determine if L-rhamnose serves as a carbon source for furaneol [134].

Unlike GC–MS, where increasing the amount of label has no general effect on detection limits, in GC–C–IRMS, increasing label enrichment in precursor compounds produces significantly improved detection limits. In a recent review of high-precision CF–IRMS, Brenna et al. discussed theoretical and practical considerations for this type of study [135]. High-precision CSIA in this type of tracer studies has been shown to possess advantages over organic GC–MS for stable isotopic tracer detection and to be

superior to radio-isotopic tracer methods in terms of dose size and analysis efficiency [136]. Guo et al. reported that GC–C–IRMS provides 15-fold lower detection limits for [$^{13}\text{C}_2\text{--C3,C4}$]cholesterol than organic GC–MS [137]. Using [$\text{U-}^{13}\text{C}$]α-linolenic acid, Sheaff et al. were able demonstrate that conversion of α-linolenate into docosahexaenoate was not depressed by high dietary levels of linoleic acid [117]. An interconversion of saturated dietary fatty acids (e.g., 18:0) into unsaturated fatty acids (e.g., 18:1) in plasma of about 14% was reported by Rhee et al. [138]. Menand et al. applied this technique to measure carbon incorporation into plasma glutamine [139]. Practical aspects of this technique have been investigated by Dube et al. [140,141].

4. Compound-specific isotope analysis of ^{15}N isotopic abundance

High precision CSIA of ^{15}N isotopic abundance faces three major challenges. First, the relatively low concentration of nitrogen in organic compounds (for instance, amino acids contain two to 11 times more carbon than nitrogen). Secondly, $^{15}\text{N}/^{14}\text{N}$ isotope ratios are measured on N_2 , which means the compound conversion step requires a reduction process and, in the case of amino acids, the formation of one mol equivalent of N_2 produces 4–22 molequivalents of CO_2 (if we regard the underivatised case). Lastly, even small amounts of atmospheric gas leaks into the instrument result in a high N_2 background.

Due to the wide spectrum of applications that would benefit from a system capable of analysing ^{15}N isotopic enrichment down to natural abundance level, especially because there is no radioactive alternative, these difficulties did not delay instrument development for too long. The desire to study for example nitrogen fixation in plants and micro-organisms and nitrogen metabolism in humans, as well as the possibility to quantify gene expression by measuring mRNA turnover, prompted two groups to extend the scope of GC–C–IRMS. In 1994, Preston and Slater presented a system with a conversion interface comprising combustion furnace, liquid N_2 cold trap, to trap CO_2 and water, and a PLOT column to resolve N_2 from any CO formed by poor combustion [142]. If CO were permitted to enter the

ion source simultaneously with N_2 , this would result in a serious isobaric interference at m/z 28. For $\delta^{15}\text{N}$ values of $t\text{BDMS}$ derivatives of amino acids, they reported a precision of S.D. ($\delta^{15}\text{N}$) = 5‰ at natural abundance level.

In the same year, Merritt and Hayes presented a similar system but for the addition of a reduction furnace, loaded with Cu wires and maintained at a temperature of 600°C, to reduce N-oxides to N_2 and to scavenge O_2 emanating from the combustion furnace [143]. Their system also included a cryogenic trap to remove CO_2 and water, and it produced a precision of S.D. ($\delta^{15}\text{N}$) = 0.2‰.

This marked difference in precision was attributed to different performances of the IRMS systems. Ongoing investigations in our laboratory seem to indicate that this difference might be caused by the simultaneous presence of NO and N_2 in the ion source. Placing a PORAPLOT Q capillary column of 0.32 mm internal diameter, maintained at 30°C between the water trap and the ion source, separates N_2 from NO (Fig. 5). Comparing precision for $\delta^{15}\text{N}$ analysis of identical aliquots from the same sample with and without the PLOT column in place, we found a drop in precision from S.D. ($\delta^{15}\text{N}$) = 0.15‰ to S.D. ($\delta^{15}\text{N}$) = 2‰, respectively. This phenomenon cannot be explained by isobaric interference of NO (m/z 30) with m/z 28 ($^{14}\text{N}_2$) or m/z 29 ($^{15}\text{N}^{14}\text{N}$) but might be caused by reaction of NO with N_2 in the ion source.

To avoid potential isotopic fractionation due to various degrees of nitrogen silylation when TMS derivatives were formed, Hoffmann et al. prepared $t\text{BDMS}$ derivatives of amino acids from wheat protein hydrolysate [144]. The same strategy was followed by Segschneider et al. when investigating ^{15}N uptake from ^{15}N -labelled NO_2 by measuring $\delta^{15}\text{N}$ values of soluble amino acids in sunflower leaves [145]. However, when preparing $t\text{BDMS}$ derivatives, one has to bear in mind that in the case of, e.g., L-leucine, one adds 12 mol equivalent of carbon to 1 mol equivalent of amino acid, thus resulting in 36 mol equivalent of carbon for 1 mol equivalent of N_2 , which might give rise to CO formation due to poor combustion. Metges et al. reported an alternative derivatisation protocol for amino acids yielding *N*-pivaloyl, *O*-isopropylates, and demonstrated their application by measuring NA

Fig. 5. The N_2^+ mass traces obtained for alanine (as *N*-acetyl, *O*-propyl derivative) having passed post-combustion through a PORAPLOT Q column, held at 30°C, shows the presence of NO next to N_2 . The CO_2 peaks are caused by the formation of CO^+ from CO_2 in the ion source.

$\delta^{15}N$ values of amino acids from plasma albumin hydrolysate [146].

CSIA of ^{15}N isotopic abundance by GC–C–IRMS has been applied to measure the effect of ibuprofen on protein synthesis using ^{15}N -labelled glycine as tracer [147]. Williams et al. used ^{15}N -labelled urea to demonstrate that *Helicobacter pylori* uses urea as a nitrogen source for its synthesis of amino acids [148]. A multidisciplinary group comprising environmental, archaeological, geological and nutritional scientists showed that differences in $\delta^{15}N$ values from soil amino acids could be used to indicate differences in land use in Bronze Age, medieval and early modern soils [149]. One intriguing observation they made was the consistently low levels of ^{15}N abundance ($\delta^{15}N < 0.0\%$ vs air) in the amino acids threonine (Thr) and phenylalanine (Phe) from soils of unmanured cereal production sites, whereas $\delta^{15}N$ values of all the other amino acids were positive. We thought this was intriguing because a similar pattern was found by Metges and Petelec when monitoring

$\delta^{15}N$ values of free plasma amino acids from fasting human subjects. With the exception of Thr and Phe, all other amino acids showed positive $\delta^{15}N$ values [150].

Mas et al. suggested that $\delta^{15}N$ values of MDMA (ecstasy) could be used for batch discrimination of ecstasy tablets [61], and Faulhaber et al. used $\delta^{15}N$ values of methyl-*N*-methylantranilate as a biomarker in the authenticity control of mandarin oils [43]. Last, but not least, GC–IRMS was used for measuring $\delta^{15}N$ values of N_2 and N_2O , separated from the same sample [151,152].

5. Hyphenated techniques

In recent years, the research efforts of different groups working in the field of GC–IRMS have focused on extending the scope of on-line CSIA towards the measurement of organic $^{18}O/^{16}O$ and organic $^2H/^1H$ isotope ratios. Consequently, research

was undertaken with the aim of high-precision measurement of two different elemental isotope ratios such as $^2\text{H}/^{18}\text{O}$, $^{13}\text{C}/^{18}\text{O}$ and $^{13}\text{C}/^{15}\text{N}$, from the same compound source in one analytical run.

By placing a PORAPLOT Q capillary column between the combustion reactor and the IRMS (which enabled us to separate N_2 from CO_2 by 100 s baseline to baseline), $^{15}\text{N}/^{14}\text{N}$ and $^{13}\text{C}/^{12}\text{C}$ isotope ratio from alanine, leucine and phenylalanine could be measured in one single analysis [153]. The excellent separation of N_2 from CO_2 provided ample time to switch IRMS ion source parameters from N_2 - to CO_2 -mode (Fig. 6).

In 1994, using a GC-based IRMS system, Brand et al. showed that CSIA of $^{18}\text{O}/^{16}\text{O}$ ratios was possible by converting oxygen-containing organic compounds on-line to CO by means of a pyrolytic reaction [154]. The on-line coupling of GC and IRMS via a pyrolysis interface (GC-Py-IRMS) was used for the simultaneous determination of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values for vanilla from different origins [155]. Farquhar et

al. converted bulk plant matter into N_2 and CO by an automated on-line pyrolysis-based reaction using nickelized carbon at about 1100°C and separating N_2 from CO post-pyrolysis in a GC fitted with a 5-Å molecular sieve PLOT column [156].

Independently, Begley and Scrimgeour reported on high-precision $\delta^2\text{H}$ and $\delta^{18}\text{O}$ measurement for water and VOCs by using 20% nickelized carbon to generate both H_2 and CO at temperatures of between 1050 and 1100°C [157]. Precisions were S.D. ($\delta^2\text{H}$) = 2‰ and S.D. ($\delta^{18}\text{O}$) = 0.3‰ for samples ranging from urine, water and VOCs. Their pyrolysis system was based on earlier work that was aimed at simultaneous $\delta^2\text{H}$ and $\delta^{18}\text{O}$ determination from small water and urine samples ($0.5\ \mu\text{l}$) [158]. Common to both studies was the use of a novel IRMS with the high dispersion necessary for separation of the $^2\text{H}^1\text{H}^+$ and $^4\text{He}^+$ ion beams. This novel high mass dispersion IRMS has been described in detail by Prosser and Scrimgeour [159]. Very recently, this high mass dispersion IRMS was coupled to a

Fig. 6. Dual isotope measurement of $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ from alanine (as *N*-acetyl, *O*-propyl derivative) during the same analysis. The arrow indicates when the ion source parameters were switched from-nitrogen mode ($m/z\ 28$) to carbon dioxide mode ($m/z\ 44$). A 100-s baseline to baseline separation of N_2 from CO_2 was achieved by passing the combustion products past-reduction through a PORAPLOT Q column, held at 35°C . The results obtained from dual-isotope analyses ($\delta^{15}\text{N}$, $-7.78 \pm 0.10\text{‰}$ vs air; $\delta^{13}\text{C}$, $-40.22 \pm 0.14\text{‰}$ vs PDB) were in good agreement with those obtained from separate analyses ($\delta^{15}\text{N}$, $-7.86 \pm 0.38\text{‰}$ vs air; $\delta^{13}\text{C}$, $-40.20 \pm 0.21\text{‰}$ vs PDB).

GC via a pyrolysis interface including a 5-Å molecular sieve PLOT column to achieve CSIA for ^2H of fatty acids. Preliminary $\delta^2\text{H}$ values for 16:0 and 18:1 fatty acids (as methyl esters) from tuna oil given in a Technical Brochure were -148.5 ± 4.1 and $-155.3 \pm 1.0\text{‰}$ (vs. VSMOV), respectively [160].

A different approach to CSIA for H of organic compounds such as ethyl benzene and cyclohexanone was published by Tobias and Brenna. Initially using a two-stage reactor interface (CuO at 850°C followed by Ni held at 950°C) [161] they found that better precision for $\delta^2\text{H}$ was achieved by employing an empty alumina tube held at about 1150°C [162]. Because their IRMS was not capable of fully resolving analyte $^2\text{H}^1\text{H}$ from excess ^4He carrier gas, they used a heated Pd filter in conjunction with a make-up pressure unit to prevent He from entering the IRMS while selectively admitting only hydrogen through the Pd foil membrane into the ion source [163].

The measurement of intramolecular variations in isotopic abundance due to kinetic isotope effects during biosynthesis is another recent development to extend the scope of GC-IRMS. The group around Schmidt employed ^{13}C isotope pattern analysis for distinction of natural compounds from corresponding synthetic products [53,164]. In 1997, an on-line pyrolysis system for position-specific isotope analysis (PSIA) of selected compounds from a complex mixture was described in detail by Corso and Brenna [165]. They coupled a GC (GC-1) for sample separation prior to pyrolysis to the GC (GC-2) separating pyrolytic products of the selected sample compound. Furthermore, they installed a valve into GC-2 to permit separated pyrolysis fragments to be admitted to an organic MS for structure analysis of these fragments.

6. Conclusions

Despite recent advances, many fundamental challenges for improved instrumentation still remain, most notably developments leading to (a) quantitative sample conversion to achieve high-precision CSIA for nitrogen; (b) routine CSIA of hydrogen isotopes after gas chromatographic separation; and (c) the routine application of PSIA to detect intramolecular isotope patterns. Continuing improve-

ments in accuracy, precision and abundance sensitivity of GC-IRMS, accompanied by increased user-friendliness, will ensure that this technique will cement its role as an important and unique tool of analytical mass spectrometry.

The sheer number of applications, as well as their wide spectrum clearly demonstrates that state-of-the-art GC-C-IRMS instruments are already powerful tools providing quantitative and qualitative information that cannot be obtained by other means.

Routine Analysis by High Precision Gas Chromatography/Mass Selective Detector/Isotope Ratio Mass Spectrometry to 0.1 Parts Per Mil

James A. Hall*, Johannes A. C. Barth and Robert M. Kalin

Environmental Engineering Research Centre, Department of Civil Engineering, Queens University Belfast, Belfast BT7 1NN, N. Ireland

Stable isotope methods are potentially quite useful for validating natural or enhanced mineral degradation of contaminants. For this reason, a continuous flow gas chromatograph (GC), isotope ratio mass spectrometer (IRMS) has been coupled with a quadrupole mass selective detector (MSD) to allow simultaneous mass spectral and stable carbon isotope ratio data to be obtained from a single chromatographic analysis. This allows the target contaminant and any extra-cellular degradation intermediates to be both qualified and quantified. Previously acceptable limits of precision (0.3 parts per mil) are undesirable given the small fractionation observed during aerobic degradation. To further understand the fate of organic contaminants and to gain information about the metabolic degradative pathway employed by a microorganism, routine isotopic analyses on a range of analytes have been performed. Quantities of sample producing mass-44 ion beam signal (I^{44}) of 2×10^{-10} to 1×10^{-8} A were analysed. When the IRMS was tuned for high sensitivity, ion source nonlinearities were overcome by peak height correction from an algorithm that was produced using known isotopic standards of varying concentrations. This led to sample accuracy of $<0.01\%$ and sample precision of 0.1% . Copyright © 1999 John Wiley & Sons, Ltd.

Received 26 January 1999; Revised 15 March 1999; Accepted 17 March 1999

The ability to elucidate small differences in the stable carbon isotopic composition of organic compounds by means of isotope ratio mass spectrometry¹ provides a powerful tool in studying processes that may discriminate one stable isotope over another. Biological isotope fractionation² opens a range of potential applications for this technique. This means that isotope effects can be used as a powerful tool for gaining information about chemical reactions and enzyme-catalysed degradation steps.^{3–5} A major development in the field was the coupling of a gas chromatograph (GC) to an IRMS⁶ by the introduction of a combustion interface (C). The principle difference between a standard IRMS and a GC/IRMS was the continuous on-line nature of the latter. Organic samples of interest can now be isolated and oxidised on-line by passing them through a copper oxide combustion tube. The combustion products are then purified to leave only target CO_2 derived from the sample carbon. This is fed directly into the IRMS, allowing separation and rapid determination of isotopic ratios for a range of organic compounds in complex matrices. However, this innovation initially compromised the precision of the instrument. Instrumental differences from dual inlet mass spectrometers meant that precision of the initial GC/IRMS and later described instruments⁷ of 0.5% was lower than the

$<0.1\%$ reported for the dual inlet instruments.² Reasons for the decrease in precision^{7,8} included:

- the difference in ion beam size between the reference peak and the sample peak due to the capability of the GC/IRMS to analyse a range of analytes from one sample,
- the quality and size of the combustion tube packing, and
- the performance and design of the cryogenic water trap.

It is therefore obvious that a better understanding of possible instrumental effects will be advantageous to any analytical system⁹ especially when it has the complexities of two or more instruments coupled together.

An IRMS has applications in a large area of environmental monitoring.^{10,11} However, the complexity of bio-remediation systems presents a large variety of possible compounds present in the sub-surface as target contaminants¹² and/or secondary metabolic breakdown products. It would therefore be beneficial to have an analytical system that provides structural information as well as accurate, precise carbon isotopic information about a target analyte from a single sample. Meier-Augenstein *et al.*¹³ described an instrument capable of performing this dual analysis by coupling an ion trap detector to a GC/C/IRMS. Our aim was to couple an existing GC/mass selective detector (MSD) system to an IRMS detector thus incorporating a quadrupole detector rather than an ion trap detector as described previously.¹³ Furthermore, it is desirable to achieve accurate and precise results over a large range of sample sizes.

Figure 1. Instrument setup: 1 Injection port, 2 Gas chromatographic column, 3 a, b Split valves, 4 MSD with quadrupole filter, 5 Heart split valve, 6 Sample line helium, 7 combustion tube, 8 water trap, 9 Reference gas, 10 IRMS.

Metabolic intermediate products from degradation pathways can be formed in small amounts¹⁴ or be present for a short period of time.^{15,16} Sample considerations, coupled with the problem that some of the original chromatographic sample is diverted to the MSD, necessitates analysis of small samples producing mass 44 ion beam signals (I^{44}) between 1×10^{-10} and 1×10^{-8} A. At the time of writing the manufacturer's recommendation is that, after optimisation, analysis is only non-signal dependent over one order of magnitude (1×10^{-9} to 1×10^{-8} A).

In this paper we describe a GC/IRMS system coupled with a mass selective detector (MSD) that provides routine quantitative and qualitative analysis from the MSD and rapid carbon isotopic analysis using the IRMS (Fig. 1). We also outline a series of analyses on a variety of compounds and the development of a simple correction to allow routine analysis of trace compounds ($I^{44} = 2 \times 10^{-10}$ – 1×10^{-8} A) to an accuracy of 0.01‰ and to a precision of 0.1‰.

EXPERIMENTAL

Instrumentation

Figure 1 outlines the GC/MSD/IRMS system currently operating in the Environmental Research Centre (EERC) at Queen's University Belfast. The chromatographic unit is a CE 8000 Top gas chromatograph fitted with a Cryo 820 sub-ambient oven temperature unit (Thermoquest, Milan, Italy). The column effluent is then split inside the oven by a SGE GVF16-(2)004 ferrule (Fig. 1, item 3a). One output from this ferrule flows into the MD800 mass selective detector (Fig. 1, item 4) via a measured length of fused capillary tubing. The second effluent flow is connected to a second SGE GCF16(2)004 ferrule (Fig. 1, item 3b). This then splits the flow into two further capillaries. One of the capillaries flows into the heart split valve (Fig. 1, item 5) and the other into the combustion interface (Fig. 1, item 7). The sample is oxidised by fine CuO granules (0.61 mm) and passed through a cryogenic water trap (Fig. 1, item 8). This removes water from the oxidation products allowing purified CO₂ to flow into a bench-top VG Isoprime® IRMS (Micromass UK Ltd., Manchester, UK) (Fig. 1, item 10).

Standard preparation

Four compounds, decane, undecane, dodecane and methyl decanoate, (VG mix, obtained from Micromass UK Ltd.) were dissolved in hexane (15 ng/mL). This is used as an internal laboratory standard and routinely analysed as a quality assurance/control (QA/QC) to check the system.

Isotopically known Carrara marble¹⁷ derived CO₂ standards were made by dissolving a powdered aliquot of Carrara marble in excess phosphoric acid (95%). The acidification for the liberation of CO₂ was carried out in pre-evacuated, gas-tight vials. The vials were then kept at 25 °C for at least 4 hours to ensure CO₂ evolution under equilibrium conditions.

The phenol standards were obtained by dissolution of pure compound in ethyl acetate (0.47 mg/mL). The $\delta^{13}\text{C}$ value of phenol was also measured on a Prism III dual inlet IRMS. Ethyl acetate was used as the solvent to compare with the phenol extraction method used to study phenol utilisation and isotopic fractionation.¹⁸

Chromatographic conditions

The VG mix and phenol samples were injected with varying split ratios (30:1–166:1) and sample sizes (1–10 µL) to give the desired I^{44} intensity. Investigations have shown that split injection causes no isotopic fractionation.⁹ The CO₂ samples were injected in split mode using a gas-tight syringe. Helium (3 mL/min) was used as the carrier gas. The GC columns used were a DB5® 15 m × 0.22 mm (J & W Scientific, Folsom, CA, USA) for organic samples and a CP-Molsieve 5 Å 25 m × 0.32 mm (Chrompack, Middelburg, The Netherlands) for CO₂ samples.

RESULTS

Instrumental conditions

The identification of an analyte by its mass spectrum and the carbon isotopic ratio obtained from the same compound are unambiguously linked, because both sets of information are obtained from one injection. Figure 2 suggests that the column effluent is split effectively between the two detectors. The nonlinear trend between MSD and IRMS peak areas is thought to be an artefact of the MSD response

Figure 2. Trend of the peak areas of the IRMS and MSD.

Table 1. Measured $\delta^{13}\text{C}$ values of analytes at constant ^{44}I beam ($2\mu\text{L}$ injection, split 20:1) in comparison to their theoretical values including retention times (R_t) on the MSD and IRMS

$^\dagger 1\sigma$ - one standard deviation.

to increasing sample size. The MSD response is not linear above 1.4×10^7 total ion count (TIC) and this therefore creates the nonlinear effect at higher sample concentrations seen in Fig. 2.

Although the column flow is split and forced to flow through an excess length of capillary ($40\text{ cm} \times 75\text{ }\mu\text{m}$), the chromatographic resolution is not degraded. Likewise, despite being split twice by union valves, the resolution of the spectrum from the IRMS is not impaired, nor the integrity of the isotopic data harmed (Table 1). The main difficulty in using an MSD as a second detector with a GC-IRMS is obtaining the correct pressure balance.

With a normal GC-IRMS system, after solvent peak elution, the heart split valve closes, the sample line helium builds up a back pressure and forces the column effluent to flow with this excess helium along the combustion interface to the IRMS detector. However, we have added an extra capillary from the MSD that exerts a negative pressure on the initial split at the end of the column. This subsequently creates a delicate balance between three exerting pressures: (1) the negative pressure created by the MSD, (2) the pressure flow of column effluent, and (3) the pressure flow of sample line helium.

The balance of these pressures can be calculated using Eqn. 1 or empirically. A major problem to be noted was the

difficulty in placing the two capillaries in the union on the opposite side of the column fitting to achieve a balanced flow to both the MSD and the second split. Once this was achieved, the ideal column flow was elucidated ($2.0\text{--}3.5\text{ mL/min}$) to maintain chromatographic integrity and speed of analysis. The length of capillary from the first split to the MSD interface had to be of the correct diameter to maintain laminar flow. The relationship is outlined in the following modified Poiseuille's equation:

$$V_0 = 50747 \cdot \frac{d^4}{\eta l} \cdot \frac{\{(p_i + 14.7)^2 - (p_o + 14.7)^2\}}{(p_o + 14.7)} \cdot \frac{p_o}{p_m} \cdot \frac{(t_m + 273)}{(t_c + 273)} \quad (1)$$

where V_0 is the carrier gas volume (mL/min), η is the dynamic viscosity of the carrier gas (micropoises), l is the length of the capillary column (m), p_i is the carrier gas inlet pressure above atmospheric (psi), p_o is the carrier gas outlet pressure (psi), p_m is the pressure at which the measurement is made, t_m is the temperature at which the measurement can be made ($^\circ\text{C}$) and t_c is the temperature in the column. The important factor to note from Eqn. 1 is that the relationship between flow through the capillary and the diameter is proportional to d^4 . This means that for a small decrease in the diameter of the capillary to the MSD we observe a substantial decrease in the effective vacuum exerted on the split union.

Organic samples

Initially the VG mix was used to calibrate the instrument. The IRMS I^{44} sensitivity is greatly variable depending on variations in the set of source tuning parameters. This, coupled with the fact that the flow is split at the injection port, first union, and at the open split at the end of the combustion tube, suggests that the absolute mass of carbon entering the IRMS source is difficult to quantify. The sample is therefore described as nmoles on-column. A common term encountered in the literature describing the performance of an IRMS instrument is the 'linearity'.¹⁹ It is the authors' opinion that this term is vague and incorrectly used. The term 'linear' should describe the fact that the ion beam intensity is related by a linear (1st order polynomial) variation to the $\delta^{13}\text{C}$ value produced by that signal. IRMS manufacturers and operators generally use the term 'linear' to mean that the measured $\delta^{13}\text{C}$ value produced by the IRMS is independent of I^{44} intensity. A more correct term for this is signal independence and this is used herein. Table 1 shows that a $2\mu\text{L}$ injection at a split of 20:1 of VG mix (1.5 ng on-column) is required for an I^{44} of $6.5 \times 10^{-9}\text{ A}$. This is well within the manufacturer's specified signal independent range. The carbon isotopic ratios of the four compounds showed an average precision of 0.09% (1σ) and an accuracy error of $<0.03\%$. Table 1 also shows that the retention times on both detectors were very reproducible.

As stated earlier, our analytical system consists of a GC coupled to two detectors. It is therefore of prime importance to optimise the sensitivity of the IRMS to counter the effect of the extra split of column effluent to the MSD (Fig. 1, item 3a). This was achieved by setting the source tuning parameters to values that assured a high sensitivity response. The tuning parameters manipulated were the extraction voltage, half-plate differential voltage, z focus, ion repeller and electron volt setting.

Results outlined below demonstrate that the instrument

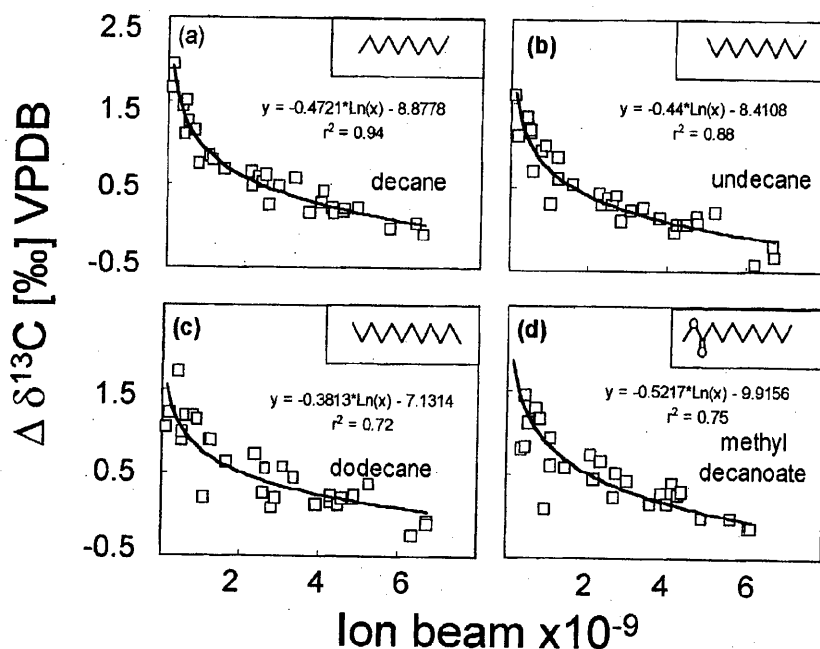

Figure 3. Ion beam strength versus the difference in isotopic composition between measured and theoretical values ($\Delta \delta^{13}\text{C}_{\text{DIC}}$) for decane, undecane, dodecane and methyl decanoate. The upper right corner of each graph shows the structure of the analyte.

produced $\delta^{13}\text{C}$ values that were signal dependent. Our initial investigations showed that although the $\delta^{13}\text{C}$ values produced for the VG mix were approximately non-signal dependent to $\pm 0.3\text{‰}$ for the ion beam intensities between 1×10^{-9} and 1×10^{-8} A, the sample accuracy and precision soon degraded significantly between 1×10^{-10} and 1×10^{-9} A. A series of injections was undertaken to produce I^{44} intensities of between 1×10^{-10} and 8×10^{-8} A. Figure 3 illustrates that the $\delta^{13}\text{C}$ values produced for decane, undecane, dodecane and methyl decanoate are exponentially dependent on the I^{44} intensity. The delta value (Δ) plotted represents the difference between the theoretical value given by Micromass UK Ltd. and the values recorded by the IRMS. All four compounds showed a positive Δ of between 1.6 and 2‰ when the ion beam signal was smaller than 5×10^{-10} A. This enrichment decreased with increasing I^{44} intensity. Figure 3 demonstrates that the theoretical $\delta^{13}\text{C}$ value is approached when the I^{44} intensity is between 5.5×10^{-9} and 7×10^{-9} A. This is because the $\delta^{13}\text{C}$ value of the reference gas used in the IRMS was cross-calibrated using VG mix at I^{44} intensities of 6×10^{-9} to 6.5×10^{-9} A. The relative molecular masses of these compounds varied from 142 to 172 Da. The logarithmic regression observed in Fig. 3 does not appear to be mass dependent. The MSD successfully identified all compounds plotted in Fig. 3 to at least a 93% confidence level.

Bioremediation of phenol is currently ongoing within the EERC.¹⁸ Phenol was therefore selected to study the effect of signal intensity on the $\delta^{13}\text{C}$ value recorded for a smaller molecule. Sample sizes analysed were again varied to produce I^{44} intensities of 1×10^{-10} – 1×10^{-8} A. Figure 4(a) illustrates that the $\delta^{13}\text{C}$ values produced were again

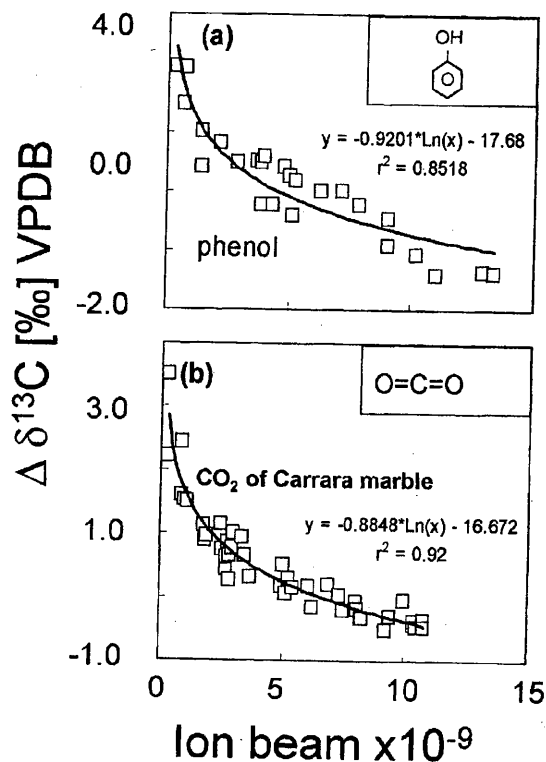

Figure 4. Ion beam strength versus the difference in isotopic composition between measured and theoretical values ($\Delta \delta^{13}\text{C}_{\text{DIC}}$) for phenol and CO_2 from Carrara marble. The upper right corner of each graph shows the structure of the analyte.

signal dependent. The $\delta^{13}\text{C}$ value becomes more enriched with decreasing sample size, reaching a maximum enrichment of 1.2‰ at an I^{44} intensity of 7×10^{-10} A. The theoretical $\delta^{13}\text{C}$ value of phenol (−28.5‰) is approached when the I^{44} intensity is 6.8×10^{-9} A.

CO₂ standards

Our aim was also to investigate the role of the combustion tube in the signal dependence trend observed. A series of CO₂ analyses derived from the acidification of Carrara marble were performed. Injecting CO₂ directly onto the column with identical operational conditions for the combustion interface obviously negates the necessity of CuO in the combustion interface to oxidise the carbon present in the sample. Figure 4(b) shows the $\delta^{13}\text{C}$ value plotted against ion beam size. The Carrara marble standard shows a maximum enrichment of 2.5‰ for an ion beam size of 3×10^{-10} A. The true value of the standard (2.4‰) is approached for an ion beam size of 6.5×10^{-9} A.

DISCUSSION

This investigation outlines the successful coupling of two independent detectors, an MSD and an IRMS to a GC. When using standard gas chromatography/mass spectrometric analysis it is important to optimise the detector to enable quantification and qualification of the smallest possible sample size. The IRMS used in our system has been optimised to operate at a high sensitivity. This now enables the quantification, qualification and $\delta^{13}\text{C}$ values of compounds to be recorded from one sample analysis.

After compromising the signal independence by tuning the IRMS for higher sensitivity, a logarithmic relationship occurs between the $\delta^{13}\text{C}$ value and the I^{44} intensity for all four compounds in Fig. 3. By manipulating the equation best describing the points ($y = m \cdot \ln(x) + c$) in Fig. 3, Eqn. 2 is derived:

$$\delta^{13}\text{C}_{\text{true}} = \delta^{13}\text{C}_{\text{actual}} - ((m \cdot \ln(I^{44})) + c) \quad (2)$$

We were then able to correct the $\delta^{13}\text{C}$ values obtained for any I^{44} between 2×10^{-10} and 7×10^{-9} A. Using this correction equation, the compounds in Fig. 3 produced $\delta^{13}\text{C}$ values to an accuracy of <0.01‰ and a precision of between 0.13 and 0.23‰. Corrected phenol $\delta^{13}\text{C}$ values were also calculated using Eqn. 2. Over two orders of magnitude the accuracy using this technique is <0.01‰ with a precision of 0.3‰. This precision is not particularly good. This could be an artefact of sample degradation over time. The results were obtained over two days and phenol has been shown to degrade as a function of time in ethyl acetate.²⁰

The $\delta^{13}\text{C}$ values of the organic compounds investigated all display a signal dependence relative to I^{44} intensity. A possible source of instrumental error could be the combustion interface.⁸ To elucidate whether this may be the case CO₂ was injected directly onto the column. The Carrara marble data showed the same logarithmic signal dependence shown by compounds that were injected on-column as liquids and combusted on the CuO interface. The $\delta^{13}\text{C}$ values could therefore also be corrected by Eqn. 2. When the correction was performed, the $\delta^{13}\text{C}$ values obtained were accurate to 0.01‰ with a precision of 0.25‰ from 2.2×10^{-10} to 1.1×10^{-8} A. The IRMS does have the potential for very

good internal precision. Table 2 shows the $\delta^{13}\text{C}$ values for analysis of CO₂ from decane over a range of sample sizes. Before adjusting the $\delta^{13}\text{C}$ values for signal size, the internal precision of the instrument is 0.53‰ for a range of I^{44} between 1.2×10^{-10} to 6.6×10^{-9} A. After correction, the average of the calculated value exactly matches the theoretical value of −28.61‰, while the precision decreases to 0.13‰.

As can be seen from the equations in Figs 3 and 4, the trends for the $\delta^{13}\text{C}$ values of the compounds in the VG mix, phenol and CO₂ are similar. Figure 5 illustrates all data points recorded ($\Delta = \delta^{13}\text{C}_{\text{actual}} - \delta^{13}\text{C}_{\text{true}}$) plotted as a function of the I^{44} intensity. The r^2 value in the equation describing the signal dependence is 0.72. This suggests that an overall correction factor could be used for all data to enhance $\delta^{13}\text{C}$ accuracy and precision over the I^{44} ranges of 2×10^{-10} to 1×10^{-8} A. However, we have found from the data presented that compound specific correction achieves better results.

The data presented here clearly show that the combustion interface performance can not account for the trends outlined in this paper. The water trap, if properly maintained, is of a reliable design and is also an unlikely source of any routine error. With decreasing sample size, any air in the system, and in particular nitrogen, will become a larger proportion of the total sample size. The possible contribution of any incompletely oxidised N₂ in the form of

Figure 5. Ion beam strength versus the difference in isotopic composition between measured and theoretical values ($\Delta \delta^{13}\text{C}_{\text{DIC}}$) for decane, undecane, dodecane and methyl decanoate, phenol and CO_2 from Carrara marble plotted in one graph.

N_2O was therefore of concern. However, any addition of ionised N_2O to the I^{44} beam would produce depleted $\delta^{13}\text{C}$ values with decreasing I^{44} intensity, the opposite of the trend observed. It is interesting to note that the application of a logarithmic correction to sample size dependant $\delta^{13}\text{C}$ values has also been reported for dual inlet measurements.²¹ However, the major difference between continuous flow and dual inlet sample introduction makes the previously published explanation inappropriate. One possible explanation for the signal dependence may be mass diffusion in the IRMS source. There is a flow of CO_2 and helium (He) into the ion source. As the ratio of CO_2 to He changes (i.e. decreasing beam I^{44} strength), there may be an increasing potential to accentuate the diffusional fractionation of mass 44, 45 and 46 and therefore cause variation in residence times of these ions within the source. Further work is needed to elucidate the exact nature of the observed phenomenon.

CONCLUSIONS

A GC has been coupled successfully with two detectors, an MSD and an IRMS. The nature of the flow splits in the instrumental coupling make it desirable to achieve a higher degree of sensitivity than may normally be required when using a routine GC/IRMS. The signal dependent trend observed is similar for all the compounds studied in this paper. However, the signal dependence that occurs from a high sensitivity source tuning can be corrected for. The

results indicate that a general correction equation could be used to correct $\delta^{13}\text{C}$ values for I^{44} intensity. However, where possible, compound specific correction provides the best accuracy and precision. This allows routine continuous flow analysis using a GC/MSD/IRMS system to produce very accurate results to a precision approaching 0.1‰ over two orders of I^{44} magnitude.

Use of gas chromatography-combustion-isotope ratio mass spectrometry in nutrition and metabolic research

Wolfram Meier-Augenstein

Linking gas chromatography via an on-line combustion interface to isotope ratio mass spectrometry has opened the door to high-precision compound-specific isotope analysis. For this reason, gas chromatography-combustion-isotope ratio mass spectrometry is now increasingly employed in metabolic and nutritional research because it offers a reliable and risk-free alternative to the use of radioactive tracers. *Curr Opin Clin Nutr Metab Care* 2:000-000. © 1999 Lippincott Williams & Wilkins.

Introduction

One of the reasons for the increasing appeal of gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) is the fact that, as a result of this technology, stable isotope labelled tracers have become a viable alternative to radioactive tracers, a fact that is of particular relevance when dealing with paediatric patients. With the exception of deuterium (^2H) when used in high concentrations, heavier stable isotopes such as ^{13}C , ^{15}N and ^{18}O do not cause any adverse physiological effects, even at high enrichment levels [1]. Isotope ratio mass spectrometry (IRMS) is an analytical mass spectroscopic technology, for it provides quantitative information rather than structural information on a given compound. The application of high-precision compound-specific isotope analysis (CSIA) in nutrition and metabolic research can be roughly divided into two areas. One area of application is concerned with studies to measure the rate of intermediary metabolism, the other aims to trace metabolic pathways using labelled precursor compounds at high enrichment levels to improve detection limits. This article aims to present an overview of the work in these areas during the past 4 years. Because this is the first time that GC-C-IRMS is presented in this forum, some emphasis is also placed on the methodological aspects and constraints of this hyphenated technique.

Practical issues concerning gas chromatography-combustion-isotope ratio mass spectrometry

In contrast to organic mass spectrometers that yield structural information by scanning a mass range over several hundred Daltons for characteristic fragment ions, IRMS instruments achieve a highly accurate and precise measurement of isotopic abundance at the expense of the flexibility of scanning mass spectrometers (Table 1). Because gas chromatography-mass spectrometry (GC-MS) can be used to measure stable isotope enrichment, the question arises as to why one should embrace GC-C-IRMS. Scanning mass spectrometers use a single detector and therefore cannot simultaneously detect particular isotope pairs for isotope ratio measurement. For isotope ratio measurement, the mass spectrometer is best operated in selected ion monitoring mode (SIM) to optimize the sensitivity to selected masses. Even in SIM mode, the limited accuracy and precision of such isotope ratio measurements impose a minimum working enrichment for ^{13}C and ^{15}N of at least 0.5 atom% excess (APE) [2,3]. In other words, organic mass spectrometry cannot

provide reliable quantitative information in cases in which a low turnover or low rate of incorporation results in isotopic enrichment of less than 0.5 APE.

In contrast, GC-C-IRMS can measure isotopic composition at low enrichment and natural abundance levels. This means that minute variations in very small amounts of the heavier isotope are detected in the presence of large amounts of the lighter isotope. Because the small variations of the heavier isotope habitually measured by IRMS are of the order of -0.07 to $+1.09$ APE, the δ -notation in units of per mil (‰) has been adopted to report changes in isotopic abundance as a per mil deviation compared with a designated isotopic standard:

$$\delta_s = [(R_s - R_{std})/R_{std}] \times 1000 \text{ ‰}$$

where R_s is the measured isotope ratio for the sample and R_{std} is the measured isotope ratio for the standard. To give a convenient rule-of-thumb approximation, in the δ -notation, a ^{13}C enrichment in the range of -0.033 to $+0.0549$ APE corresponds to a $\delta^{13}\text{C}$ value range of -30‰ to $+50\text{‰}$. A change of $+1\text{‰}$ is approximately equivalent to a change of 0.001 APE and 0.0003 APE for ^{13}C and ^{15}N , respectively.

The sensitivity of GC-C-IRMS is such that tracer/tracee (mol/mol) ratios down to 10^{-5} can be reliably detected [4]; in the same review, Brenna *et al.* also provide an in-depth discussion of notations and elementary calculations

such as mass balance and pool mixing equations.

As a result of its high sensitivity, GC-C-IRMS depends on careful sample preparation and high-resolution capillary gas chromatography [5**]. Demands on sample size, sample derivatization, quality of gas chromatography separation, interface design and isotopic calibration have been discussed in a number of reviews [2,3,5**,6-8,9**].

High-precision compound-specific isotope analysis of ^{13}C isotopic abundance

The great clinical and scientific potential of ^{13}C tracer techniques for nutritional and metabolic research in paediatric patients has been discussed recently [10**]. Several comparative studies have demonstrated the considerable advantages of GC-C-IRMS in nutritional and metabolic research. Pont *et al.* [11] measured ^{13}C enrichment in the cholesterol of rabbit low-density lipoprotein after the injection of 3 mg of $[3,4-^{13}\text{C}]\text{cholesterol}$. They compared the accuracy and precision, detection limits and dynamic range (ranging from -22 to $+760$) of GC-C-IRMS and GC-MS measurements and found GC-C-IRMS to be more accurate and reproducible, especially at lower enrichment levels. Highly linear calibration curves for ^{13}C enrichment were also reported from a study with branched-chain amino acids (BCAA) [12]. In that study, slopes of 0.98 and 1.04 were observed for enrichment ranges $0-0.14$ APE and $0-$

Table 1. Typical features and specifications of mass spectrometry systems used for stable isotope analysis

| | GC-MS | Elemental analyser- IRMS | GC-C-IRMS |
|--|--|---|--|
| Sample introduction | Injection of liquid (or gaseous) sample matrix on to GC column | Solid (and dry) sample in tin capsules | Injection of liquid (or gaseous) sample matrix on to GC column |
| Sample separation | Yes, by gas chromatography | No | Yes, by gas chromatography |
| Sample manipulation before mass spectroscopic analysis | None | Combustion/reduction of sample into CO_2 and N_2 in the elemental analyser | Combustion/reduction of compounds into CO_2 and N_2 in the interface |
| Interface | Heated transfer capillary directly connected to ion source | Transfer capillary with open split | Capillary, incorporating wide bore combustion/reduction furnaces |
| Mass analysers | Quadrupole | Magnet | Magnet |
| Detector | One electron multiplier | Triple Faraday cup collector | Triple Faraday cup collector |
| Mode of charged mass | SIM, switching between e.g. M^+ and $[\text{M}+1]^+$ ($[\text{M}+1]^+/ \text{M}^+$ ratios are calculated on the basis of measured ion current) | Simultaneous detection of particles with three adjacent masses, e.g. m/z 44, 45 and 46 for $^{12}\text{C}^{16}\text{O}_2$, $^{13}\text{C}^{16}\text{O}_2$ and $^{12}\text{C}^{18}\text{O}^{16}\text{O}$, respectively | Simultaneous detection of particles with three adjacent masses, e.g. m/z 28, 29 and 30 for $^{14}\text{N}^{14}\text{N}$, $^{14}\text{N}^{15}\text{N}$ and $^{15}\text{N}^{15}\text{N}$, respectively |
| Detection | | -0.1 – $+2.0$ | -0.1 – $+2.0$ |
| Measureable enrichment range in [APE] | $+0.5$ – 100^a | | |
| Sample size requirement | $\leq 1 \text{ pmol}$ | 0.1 – $5 \text{ } \mu\text{mol}^b$ | 0.1 – 5 nmol^c |
| CSIA | Yes, with a precision of $0.05 \text{ atom}\%$ | No ^d | Yes, with a precision of $0.0002 \text{ atom}\%$ |

^aUsing a multiply labelled tracer (e.g. $[^2\text{H}_5]\text{phenylalanine}$) and measuring $[\text{M}+n]^+/ \text{M}^+$ ratios (e.g. $[\text{M}+5]^+/ \text{M}^+$), enrichments down to 0.2 APE can be reliably detected.

^bThe required sample size depends on the type of isotope analysis. Analysis of ^{13}C enrichment requires only small amounts of material because of the high abundance of carbon in organic compounds. The opposite is true for the analysis of ^{15}N enrichment, because of the low abundance of nitrogen in organic compounds. Furthermore, for compounds containing only one atom of nitrogen, two moleequivalents of compound have to be combusted to generate one moleequivalent of N_2 .

^cIn addition to the considerations mentioned above, it should be noted that compound-specific isotope analysis (CSIA) by gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) requires the injection of 0.1 – 5 nmol per individual compound to be analysed.

^dUsing elemental analyser-IRMS, CSIA is only possible for off-line isolated and purified compounds. Here, the precision is $0.001 \text{ atom}\%$. APE, Atom% excess; GC-MS, gas chromatography-mass spectrometry; SIM, selected ion monitoring mode.

8 APE, respectively. Parker *et al.* [13] showed that GC-C-IRMS permits the use of low doses of β -[U- ^{13}C]carotene (≤ 2 mg), which do not perturb endogenous pool sizes of β -carotene or retinol. Employing ^{13}C tracers at low levels of enrichment, reliable data were obtained in studies of the kinetics of glycoprotein neutral sugars [14] and urea [15]. Bunt *et al.* [16*] used [U- ^{13}C]glucose as a precursor to obtain data on endogenous surfactant production and turnover by measuring ^{13}C -enrichment of palmitic acid in phosphatidylcholine palmitate. GC-C-IRMS was also used to determine the range of natural isotope abundance of ^{13}C in six serum fatty acids from humans on a controlled diet [17].

Compound-specific isotope analysis of ^{13}C labelled fatty acids

The high sensitivity of GC-C-IRMS has been increasingly exploited in metabolic studies investigating the turnover, incorporation and synthesis processes of fatty acids *in vivo*, which could only previously be investigated either with stable isotope tracers at high enrichment levels using GC-MS, or not at all [18].

GC-C-IRMS, capable of measuring naturally occurring differences in isotope ratios, determined the extent to which neonates and very low birthweight premature infants could synthesize arachidonic acid, which is essential for their growing tissues, from dietary fatty acids. Demmelmair *et al.* [19] showed that in neonates fed on a phenylalanine-free diet, on average 23% of free plasma arachidonic acid on study day 4 originated from infantile linoleic acid conversion. Carnielli *et al.* [20] added linoleic acid and linolenic acid, both ^{13}C -labelled, to the formula diet that was administered continuously for 48 h (birthweight 1.17 ± 0.12 kg; gestational age 28.4 ± 1.3 weeks). The authors demonstrated that both tracers were rapidly incorporated into plasma phospholipids and that their metabolic products including arachidonic acid and docosahexaenoic acid became highly enriched with ^{13}C . The incorporation of ^{13}C -octanoic acid into plasma triglycerides (10% of the enrichment of the diet), noticeably into myristic and palmitic acid, by very low-weight preterm infants was reported earlier by the same group [21].

The majority of ^{13}C tracer studies published have dealt with various aspects of fatty acid biochemistry. The bioequivalence of dietary α -linolenic and docosahexaenoic acid as substrates for brain and retinal n3 fatty acid accretion during the brain growth spurt [22,23*], metabolism of triglycerides [24], transport and turnover of free saturated [25,26,27*] and unsaturated fatty acids [28–30,31*]. While studying the metabolism of ^{13}C -labelled polyunsaturated fatty acids by ^{13}C -nuclear magnetic resonance, using GC-C-IRMS, Cunnane *et al.* [32] found low levels of ^{13}C -labelled γ -linolenic acid

in the brain phospholipids of suckling rat pups that could not be detected by ^{13}C -nuclear magnetic resonance.

Unlike GC-MS, in which increasing the amount of label has no general effect on detection limits, in GC-C-IRMS, increasing label enrichment in precursor compounds produces significantly improved detection limits. Taking advantage of this increased traceability, Rhee *et al.* [33] quantified the desaturation of [U- ^{13}C]18:0 and [U- ^{13}C]16:0 in whole plasma and lipoprotein of adults after the administration of 30 mg oral doses (< 0.5 mg/kg). Su and Brenna [34*] reported the simultaneous measurement of desaturase activities by monitoring the increase in product from the reactions [U- ^{13}C]18:2n6 \rightarrow [U- ^{13}C]18:3n6 and [U- ^{13}C]16:0 \rightarrow [U- ^{13}C]16:1n7, respectively.

Using [U- ^{13}C] α -linolenic acid, Sheaff *et al.* [35] were able to demonstrate that high dietary levels of linoleic acid did not depress the conversion of α -linolenate into docosahexaenoate. Three years later, Menard *et al.* [36*] showed that [U- ^{13}C] α -linolenic acid is not solely a source of docosahexaenoic acid. They found that, owing to a high rate of β -oxidation and carbon recycling, [U- ^{13}C] α -linolenate was utilized in the de-novo synthesis of cholesterol and palmitate.

Compound-specific isotope analysis of ^{13}C -labelled amino acids

In spite of the wide usage that GC-C-IRMS enjoys in research concerned with fatty acid and surfactant metabolism, most research groups interested in amino acid metabolism and protein turnover still seem to favour traditional GC-MS methods such as SIM in conjunction with poly-deuterated tracers or tracers highly enriched in ^{13}C . This may be because GC-MS methods cannot easily be adapted to suit the particular needs of GC-C-IRMS. As mentioned above, the nature of the derivatization agent can influence the accuracy and precision of CSIA, because it will dilute ^{13}C enrichment and can adversely affect chromatographic separation and the efficiency of the combustion catalyst (cf. Table 2) [5*,7,9**].

Seemingly in response to these difficulties, most groups using GC-C-IRMS to study turnover and synthesis rates of various proteins have adopted a strategy whereby a target amino acid is identified that will act as a marker providing unambiguous and quantitative information about the system under investigation. This strategy included the development of a sample preparation protocol tailor-made for the particular amino acid allowing quick and reliable CSIA.

In this way, L-[^{13}C -1]valine was employed to measure in-vivo secretion rates of very low density lipoprotein-

Table 2. Overview of typical analytical procedures used in metabolic and nutritional research involving stable isotopes and their caveats

| Compound class | Derivatization | Typical GC conditions ^a | Caveats |
|--|---|---|---|
| Long-chain alcohols and sterols (e.g. cholesterol) | TMS | CP-Sil 5: 50°C (2 min) to 200°C at 40°/min, 200–320°C at 3°/min | None |
| Fatty acids | Methyl ester using methanol/ BF ₃ | CP-Sil 8/CP-Sil 19: 120°C (4 min) to 280°C at 4°/min | None |
| Hydroxy/amino/keto-carboxylic acids | TMS or tBDMS | CP-Sil 8: 80°C (5 min) to 150°C at 2°/min, 150–220°C at 3.5°/min; 20°/min to 300°C | TMS: multiple derivatives for same compound ^b tBDMS: excessive carbon load ^c Risk of non-quantitative derivatization ^d |
| Hydroxy/amino.keto-carboxylic acids | Ethylchloroformates | CP-Sil 24: 60°C (3 min) to 300°C at 6°/min | Risk of non-quantitative derivatization ^d |
| Hydroxy/amino/keto-carboxylic acids | Acetyl, methylates | CP-Sil 19: 70°C (5 min) to 220°C at 5°/min | None |
| Amino acids | TMS or tBDMS | CP-Sil 8: 50°C (5 min) to 150°C at 6°/min, 150–300°C at 12°/min | TMS: multiple derivatives for same compound ^b tBDMS: excessive carbon load ^c Poisoning of combustion catalyst ^e |
| Amino acids | TFA, methylates TFA, iso-propylates | CP-Sil 19: 70°C (5 min) to 180°C at 3.5°/min, 180–230°C at 5°/min; 10°/min to 270°C | |
| Amino acids | Ethylchloroformates, methylchloroformates | CP-Sil 19: 60°C (3 min) to 100°C at 5°/min, 100–300°C at 10°/min | Risk of non-quantitative derivatization ^d |
| Amino acids | N-Pivaloyl, iso-propylates | CP-Sil 8: 70°C (1 min) to 200°C at 3°/min, 220–300°C at 10°/min | None |
| Amino acids | N-Acetyl, propylates | CP-Sil 19: 70°C (5 min) to 200°C at 4°/min, 200–300°C at 6°/min | None |

^aThe content of this column should be read as generalized guidelines providing a starting point for the reader to resolve individual analytical tasks. Information provided is choice of gas chromatography (GC) column (=stationary phase) and temperature programme. CP-Sil is a proprietary name of CHROMPACK International BV (Middelburg, the Netherlands) and has been chosen as an example because it is widely recognized.

^bAmbiguity of results; a problem for gas chromatography-mass spectrometry (GC-MS) as well as gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS).

^cStrong dilution of ¹³C enrichment; this affects only GC-C-IRMS measurements. It is, however, only a problem when the measurement cannot be compared against the background or baseline ^{δ13}C value of an authentic sample.

^dPotential loss of information (GC-MS and GC-C-IRMS).

^eA serious problem for GC-C-IRMS; leads ultimately to incomplete combustion and can negatively affect the accuracy and precision of ¹³C and ¹⁵N isotope abundance measurements.

TFA, Trifluoroacetyl; TMS, Trimethylsilyl; tBDMS, tert-Butyldimethylsilyl.

apolipoprotein B100 in humans [37*], synthesis rates of α_2 -macroglobulin in nephrotic patients [38*] and the protein fractional synthetic rate in skeletal muscle [39*] and plasma albumin [40*].

In the same way, other groups used L-[¹³C-1]leucine to measure the fractional synthesis rate of mixed muscle protein, myosin heavy chain and actin in human skeletal muscle [41*,42], the metabolism of human apolipoprotein B [43] and protein synthesis in patients suffering from rectal cancer [44,45].

To measure collagen synthesis in adult humans, Rennie *et al.* [3] used L-[¹³C-1]proline with an enrichment of 30 mol% excess as the marker amino acid. The usefulness of proline as a tracer lies in the phenomenon of post-translational hydroxylation of collagen-bound proline into 4-hydroxyproline and the fact that all protein-bound 4-hydroxyproline is in collagen.

Menand *et al.* [46] described a method to determine low enrichment levels of free L-[¹³C-1]glutamine in plasma, and Meier-Augenstein *et al.* [12] reported a method to measure [¹³C-1]-labelled BCAA L-valine, L-leucine and L-isoleucine, as well as their transamination products in

human plasma after oral bolus administration. The authors demonstrated that this method could be used to measure whole-body BCAA oxidation in patients suffering from maple syrup urinary disease [12].

High-precision compound-specific isotope analysis of ¹⁵N-labelled amino acids

Published work on studies of amino acid and protein turnover using ¹⁵N isotopic abundance measurements by GC-C-IRMS are still few and far between. This is quite probably a reflection of the analytical challenges associated with high precision CSIA of ¹⁵N isotopic abundance in amino acids. First, the low concentration of nitrogen in amino acids, for amino acids contain two to 11 times more carbon than nitrogen. Second, ^{δ15}N measurements require N₂, which at least doubles the sample size requirement because two molequivalents of amino acids are needed for the production of one molequivalent of N₂. Non-quantitative sample conversion and reduced sensitivity of the IRMS ion source for N₂ (compared with CO₂) increase sample size requirements further, by a factor of five compared with CSIA of ¹³C-labelled compounds. Finally, even small amounts of atmospheric gas leaks into the GC-C-IRMS instrument result in a high N₂ background level.

However, CSIA of nitrogenous compounds such as amino acids yields new and unexpected insights into the metabolism of organic nitrogen. For example, a study of plasma albumin synthesis using L-[^{13}C -1, ^{15}N]alanine and L-[^{13}C -1, ^{15}N]leucine showed that both amino acids underwent transamination (and re-amination with nitrogen from the body's nitrogen pool) before their incorporation into plasma protein [3]. The observed enrichment ratios of $^{15}\text{N}/^{13}\text{C}$ found in plasma albumin were 1:3.18 and 1:2.29 for alanine and leucine, respectively. A cross-over of ^{13}C could be ruled out because $\delta^{13}\text{C}$ -values for simultaneously administered L-[^{13}C -1]phenylalanine remained at baseline level throughout the course of the study.

Preston *et al.* [47] measured protein synthesis using [^{15}N]glycine to study the effect of ibuprofen on the plasma concentration of acute-phase proteins in patients with colonic cancer. The authors found that ibuprofen caused a significant reduction of all five acute-phase proteins (fibrinogen, C-reactive protein, caeruloplasmin, α_1 -antitrypsin and α_1 -acid glycoprotein) after 3 days of oral ibuprofen.

Monitoring $\delta^{15}\text{N}$ -values of free plasma amino acids from fasting human subjects, Metges and Petzke [48] made the intriguing observation of consistently low levels of ^{15}N abundance ($\delta^{15}\text{N} < 0.0\text{‰}$ versus air) in the amino acids threonine and phenylalanine. The $\delta^{15}\text{N}$ values of all the other amino acids were positive ($\delta^{15}\text{N} > 0.0$ versus air). In subsequent studies that involved the administration of oral bolus doses of [$^{15}\text{N}_2$]urea, Petzke *et al.* [49] found that incorporation of ^{15}N from this source into plasma protein amino acids was consistently low for lysine, histidine, proline and phenylalanine. On the basis of the results of a widened study combining the administration of [$^{15}\text{N}_2$]urea with the ingestion of lactic acid bacteria, Petzke *et al.* [50] hypothesized that these low levels of ^{15}N incorporation suggest only limited or no participation in the transamination reactions of those amino acids.

Conclusion

High-precision CSIA by GC-C-IRMS of organic compounds at natural abundance and low enrichment levels is a powerful tool that provides new insights as well as quantitative information on human metabolism. GC-C-IRMS is a unique tool that can provide answers to biochemical and physiological questions that cannot be obtained by any other analytical instrumentation.

Progress Report

March 2004

**Project: Statistical Population Studies to Support New Analytical
Methodologies using the EPO2000 Project Urine Samples.**

Investigators

R. Kazlauskas, G. J. Trout, C. Howe and J. Rogerson (Australian Sports Drug
Testing Laboratory)

SUMMARY

This report outlines the progress so far in our statistical population studies which are designed to provide a firm basis for two relatively new forms of sports drug testing; namely the use of carbon isotope ratio mass spectrometry (CIRMS) for detecting the abuse of endogenous anabolic steroids, and the use of isoelectric focussing to detect the abuse of erythropoietin (EPO). The techniques are very different in methodology and application but both rely on detecting small but significant differences between truly endogenous compounds and their synthetic variants. In order to reliably detect doping with either technique it is essential that the extent of natural variation in the elite athlete population be known. Criteria have been set which are already being used to detect doping but so far no large-scale study has been carried out to test these criteria over a wide range of elite athletes. Our study will provide this information which will not only support the validity of the tests but may also result in improvements in the criteria leading to a more robust and sensitive testing program.

The progress so far is to schedule with over 70% of the samples being analysed for ketosteroids for part 1 of the study (CIR measurements) and almost 70% of the samples being completed for part 2 of the study (EPO glycoforms). The most significant single finding is that the criteria currently in use are entirely appropriate for doping control since no false positives have been found for either method in the hundreds of samples analysed. However preliminary analysis of the CIRMS data has shown that it may be desirable to modify the criteria used to enhance the detection of endogenous anabolic steroids depending on the athletes natural levels. This would be done without compromising the selectivity of the method.

It is anticipated that all goals of the first year of the project will be met on time and within budget. The program for 2004-2005 will result in the completion of part 2 of the study by September 2004 with preparation of a scientific paper on the EPO glycoform study. The second phase of the CIR measurements will begin with analysis of the steroidal diols. During the year a paper will be prepared presenting the data obtained from the completed keto steroid phase of the project.

BACKGROUND

It was recognised in the early stages of the development of an indirect test for detecting recombinant human EPO that it was essential to establish the range of variability expected for all the relevant parameters in a large group of elite athletes. Multiple samples of blood and urine were collected from over 1100 athletes and are currently stored frozen. At the time of the collection it was recognised that the samples represented a valuable resource which could be required to validate future tests for endogenous compounds. Thus the ethics approval obtained from each subject permits the samples to be used in research on the detection of doping with EPO and endogenous steroids. The samples were collected in 12 countries with representation of all major ethnic groups. Because of repeat urine collections there are some 2000 urine samples in total. The factors related to each sample which have been recorded include gender, ethnicity, age, sport, altitude and time since exercise. The sample size and diversity is such that it should be possible to determine if there are any significant effects of gender, ethnicity, exercise, sporting discipline, altitude and biological variation.

The detection and confirmation of the presence of ingested or injected endogenous steroids using CIRMMS is based on the fact that the synthetic versions of the steroids have a lower proportion of carbon 13 resulting in more negative delta ¹³C values compared with naturally produced steroids. Typically synthetic steroids have delta values close to -30 whilst the delta value of natural circulating steroids are typically -22 to -24. The CIRMMS methods used to detect doping measure the delta values of steroid metabolites and compares them to the values found for precursors. The premise on which the method is based is that in a normal individual the delta values of the precursors and the metabolites will be similar. Actual measurement of these values in a wide range of subjects will provide the sound statistical basis on which to base the criteria used for determining a positive doping case.

The current method used to confirm doping with human recombinant EPO is based on the fact that recombinant EPO is significantly less acidic than urinary EPO despite the recombinant product being produced from mammalian cells containing the human gene. This difference in acidity arises from the fact that the recombinant product is less glycosylated and has fewer sialic acid residues than normal urinary EPO. In the normal human body EPO is produced in the kidney in response to low levels of oxygen in the blood. The glycosylation of the EPO protein is needed to allow it to circulate to the bone marrow where it stimulates the production of new red blood cells. The EPO protein is rapidly destroyed and is not effective if injected in the deglycosylated form. The protective effect of the sugar moieties has been extended in the new Amgen product Aranesp, which has the EPO protein modified so that two additional sugar chains are introduced. This has the effect of significantly increasing the half life of the circulating material (Egrie and Browne 2001). Although much is known of the structure of the isoforms of recombinant EPO from mass spectral and other measurements

(Ohta et al 2001) what data there is on the structure of natural EPO comes from a very few subjects. In fact virtually all the data available on the variability of natural EPO isoforms has come from the few IOC laboratories that are currently routinely performing the EPO urine test. Since the urinary EPO test is critically dependent on the difference in glycosylation between natural and recombinant EPO, it is essential to be aware of the extent of natural variability of this glycosylation in the general population of elite athletes.

AIMS

The aims of the project are twofold. Using urine samples already collected from a large cohort of ethnically and geographically diverse elite athletes we intend to:

- A. Determine the variability in the isotope ratio of some selected endogenous steroid metabolites and evaluate whether the delta ^{13}C values are significantly affected by factors such as gender, ethnicity and geographical location.
- B. Determine the variability of the natural isoform pattern of urinary EPO and evaluate whether the patterns are significantly affected by factors such as gender, ethnicity and altitude.

As there are essentially two separate projects within the one grant application the results for each have been reported separately.

Part 1 CIR measurements

Experimental Methods

A method used has been developed for the extraction of the endogenous steroids androsterone (A), etiocholanolone (Et), 11-ketoetiocholanolone (11-keto), and their measurement using CIRMS. After hydrolysis with β -glucuronidase the free steroids are extracted from the urine using BondElut Certify SPE columns. The extracts are analysed by GC-CIRMS using a Finnigan-MAT Delta Plus with a Hewlett-Packard 6890 GC. The calculations of isotopic ratio are made using ISODAT 7.4 software. The $\delta^{13}\text{C}$ values for the steroid metabolites A and Et, and the precursor 11-keto have been measured. The results are stored in Excel spreadsheets prior to statistical analysis.

Results

The results from the first four countries completed Australia, China, Kenya, and New Zealand comprising some 450 samples have been published (Cawley et al 2004). In summary the major findings are:

- The GC-CIRMS methodology has a high degree of precision and accuracy based on multiple measurements of the internal standard 17-MeT. The certified value determined by combustion analysis was -32.80‰, whilst the mean value found was -32.42‰ ($n > 700$), with a SD of 0.90.
- The distribution of $\delta^{13}\text{C}$ values was close to normal in all four countries.
- The $\delta^{13}\text{C}$ values and the spread of these values were similar for the Australian and New Zealand populations. This was to be expected as the dietary patterns in the two countries are similar.
- The $\delta^{13}\text{C}$ values were significantly different ($p < 0.0001$) for China (mean = -21.6), Kenya (mean = -20.3) and Australia/New Zealand (mean = -22.8). It is almost certain that the different dietary patterns are responsible for these differences.
- There was a consistent difference of approximately 2.0‰ between the average $\delta^{13}\text{C}$ values of androsterone and etiocholanolone and the value for the precursor 11-ketoetiocholanolone.
- The most negative $\delta^{13}\text{C}$ value found in any sample for androsterone was -25.1‰ and for etiocholanolone it was -25.8‰.

Implications for Doping Control

These preliminary results have a number significant implications for the use of GC-CIRMS in the detection of the abuse of endogenous anabolic steroids:-

- The precision and accuracy of the multiple measurements adds confidence to the reliability and reproducibility of GC-CIRMS measurements.

Our laboratory like many others use a combination of criteria to assess whether a sample is positive. Our current criteria are

1. The difference between the average of $\delta^{13}\text{C A}$ and $\delta^{13}\text{C Et}$ values, and $\delta^{13}\text{C 11-keto}$ must be greater than 4.0‰.
2. The ratio must be greater than 1.15.
3. $\delta^{13}\text{C A}$ and $\delta^{13}\text{C Et}$ must be more negative than -27.0‰.

All must be met for a sample to be called positive. As expected none of the samples measured so far would be identified as positive.

- The results show that the use of a difference of greater than 4.0‰ is a necessary condition to confirm doping but it is not a sufficient condition. A small number of samples had differences greater than 4.0‰ usually due to isotope enriched (less negative) values for the 11-keto. Thus far a difference of 6.0‰ would be a sufficient condition by itself to confirm doping.
- The use of the ratio of the average of A and Et values to that of the 11-keto provides no additional information and should be discontinued.
- The suggestion has been made that a cutoff value such as -27.0‰ could be used to detect the use of synthetic endogenous steroids (Aguilera et al 2000). This is supported both by the lowest value found being -25.8‰ and by the mean and standard deviation results. The lowest calculated $\delta^{13}\text{C}$ value (mean minus 3σ) is -26.5‰ for New Zealand. The $\delta^{13}\text{C}$ values for Australia, China and Kenya were all less negative.
- The combined criteria of a difference of 4.0‰ and $\delta^{13}\text{C A}$ and $\delta^{13}\text{C Et}$ being more negative than -27.0‰ is appropriate for the Australia/New Zealand populations but will result in a greater number of false negatives when applied to athletes with less negative $\delta^{13}\text{C}$ values such as those from Kenya.
- Although a full statistical analysis has yet to be carried out it is clear from the data so far that the effect of geography is far greater than any other effect including sex and sport. From the nature of human metabolism it would be expected that diet would be the major influence on steroid isotope ratios (Morrison et al 2000).

Part 2 EPO glycoforms

Experimental Methods

The urinary EPO concentrations have been measured using an EPO kit on a DPC Immulite instrument. As this method is designed for serum samples it was necessary to centrifuge each urine sample, ultrafilter it and buffer wash the retentate prior to analysis.

The urinary isoforms were measured using a variation of the original Lasne method (Lasne et al 2002). 20mL of each urine was concentrated to 30uL using two ultrafiltration devices. The concentrated samples underwent isoelectric focussing on an ampholyte gel and were then transferred with two Western blotting steps. The membrane was visualised using Pierce SuperSignal West Femto Maximum Sensitivity Substrate. The signals were recorded with a Fuji LAS-1000 camera and quantitated with Fuji Image Guage v3.41 software. Sample results are stored in an Access database.

Results

In order to properly evaluate the isoform data collected from elite athletes it was first necessary to determine what variability there was in the method itself and what variability was to expected in any one subject over time. The method variability was estimated by analysing urine samples spiked with varying levels of recombinant EPO from 0 to 15 IU/L several times on six gels run on different days. The results showed that a variation of 5 in a value of 50% basic isoforms could be expected (CV = 10%). At higher values (90% basic isoforms) the variation was less being about 3 (CV = 3%). The subject variability was determined by analysing the results from some 20 subjects who had up to 10 urine samples collected over a period of three days. The mean CV observed for the subjects was 17% which is much higher than the variation that could be attributed to the method of measurement. A large variation in urinary EPO concentrations was also observed in these subjects but there was no correlation observed between urinary EPO concentration and % basic isoforms.

Some preliminary results from the EPO2000 samples and the low risk ASDA samples have been evaluated. The table below summarises the results

| | EPO2000 | | ASDA | |
|--------------------|---------|--------|------|--------|
| % Basic Isoforms | Male | Female | Male | Female |
| Mean | 35.8 | 39.7 | 36.5 | 43.9 |
| Median | 35.5 | 37.0 | 35.0 | 44.0 |
| Standard deviation | 14.5 | 16.5 | 13.8 | 15.8 |
| Count | 100 | 50 | 163 | 47 |

The results show that the ASDA low risk routine samples and the EPO2000 samples are not significantly different in the distribution of their EPO % basic isoforms. This demonstrates the validity of including the ASDA samples in our study. From the current data there appear to be no significant effects of ethnicity on the isoform results

| % Basic Isoforms | ASDA males | Chinese males | Kenyan males |
|--------------------|------------|---------------|--------------|
| Mean | 36.5 | 37.2 | 40.3 |
| Median | 35 | 36 | 39 |
| Standard deviation | 13.8 | 17.1 | 11.2 |
| Count | 163 | 38 | 16 |

Implications for Doping Control

These preliminary results have a number significant implications for the use of urinary EPO isoforms in the detection of the abuse of recombinant EPO:-

- The reproducibility of the % basic isoform measurement using the existing amphoteric gel technique with double blotting is adequate for doping control purposes. This was determined under the worst case scenario ie. different gels prepared on different days whereas a positive sample would be measured against standards run on the same gel.
- The standard deviation of the % basic isoforms found for any given individual is approximately 17. This high individual variability means that the detection of differences relating to sport, age or sex is unlikely.
- There have been no differences observed relating to ethnicity.
- The last two findings indicate that the test should be equally applicable to all those tested.
- No positive findings have been found in the samples which indicates that the criteria used to determine doping with recombinant EPO are appropriate. Closer examination of those samples with relatively high % basic isoforms may lead to improved criteria.

Report on Progress

Part 1 CIR measurements

Summary Table

| Activity | Estimated completion in proposal | Progress thus far | On schedule Y/N |
|--------------------|-------------------------------------|--|-----------------|
| Organise logistics | July 2003 | Staff were allocated to the project in July 2003 | Y |
| Organise samples | August 2003 | Samples selected from existing sample set and sorted by country of origin and volume of sample available. ¹ | Y |
| Analyse samples | June 2004 | Approximately 900 samples have been extracted for GC-CIRMS analysis. 750 have been analysed. | Y |
| Evaluation of data | Nov/Dec 2003 and April to June 2004 | The data evaluation needed for the results entry into the database has been completed for some 700 samples from 12 countries. The statistical evaluation will begin in April 2004. | Y |
| Report to ADRP | January 2004 | Report requested in November 2003. Preliminary report submitted in December. Second report requested in March 2004. | Y |

1. The original proposal called for the analysis of most of the 2000 urine samples collected in the EPO2000 project. As there were only a little over 1100 subjects in the study many of the urine samples were duplicate collections made a week or so apart. Close examination of the samples collected has shown that not all are suitable for analysis. In addition it has been found that steroid excretion is normally stable for an individual over extended periods of time and repeat analyses from the same subject will provide virtually no additional information. As a result of these factors the number of urine samples suitable for analysis by GC-CIRMS is approximately 1050.

Part 2 EPO glycoforms

Summary Table

| Activity | Estimated completion in proposal | Progress thus far | On schedule Y/N |
|--------------------|----------------------------------|--|-----------------|
| Organise logistics | July 2003 | Staff were allocated to the project in July 2003 | Y |
| Organise samples | August 2003 | Samples selected from existing sample set and criteria established for selection of further samples. ¹ | Y |
| Analyse samples | June 2004 | Urinary EPO concentrations have been measured for over 1100 EPO2000 samples. Only one quarter of the urines had sufficient EPO present to continue with isoform analysis. The data set has been extended by using samples from the operational sample base. Over 600 of these have been screened for urinary EPO concentration and some 300 have had isoform distributions measured. | Y |
| Evaluation of data | January and July 2004 | Isoform measurements have been made but statistical evaluation is currently behind schedule. | N |
| Report to ADRP | January 2004 | Report requested in November 2003. Preliminary report submitted in December. Second report requested in March 2004. | Y |

1. In the original project proposal it was planned to use the EPO2000 urine samples to obtain the data required. However only approximately one quarter of the samples had sufficient urinary EPO present to proceed with EPO isoform analysis. This meant that there would be significantly less data available than expected. It is possible that these samples, despite being stored frozen, have undergone some degradation. Since the project was planned there has been evidence coming from several laboratories that some urine samples can change with time and produce isoform patterns that resemble recombinant EPO (Howe 2003). With fresh urines 40 to 50% have sufficient EPO to proceed with isoform analysis. For these reasons it was decided to continue the project using samples taken from the routine operational collections. Samples which have been reported negative are selected from a range of sports including some at risk endurance sports but avoiding samples where there is any indication at all from blood parameters of EPO abuse. In addition fresh urine samples have been obtained from elite athletes in Indonesia to extend the ethnic diversity and it is planned to obtain urine samples from at least one other country.

Proposed activities to June 2004

For the period up to June 30 it is anticipated that the project will continue in accordance with the schedule presented in the original project proposal. Both projects are on schedule or ahead of schedule for experimental activities. The specific activities proposed for the next months are:

- **Part 1 CIR measurements.** Extractions and GC-CIRMS analyses will continue with the intention of having approximately 1050 samples from 12 countries analysed by June 2004. Data processing and review will continue so that the statistical analysis can begin. The method for the diol analysis procedure will be finalised and validated in preparation for the second stage of the project. It appears at this stage that the method will be considerably more complex than first envisaged and the number of urine samples to be analysed will need to be reduced.
- **Part 2 EPO glycoforms** Analysis will continue so that 600 urine samples will have been tested using the gel electrophoresis method. It is anticipated that at least 25% of the samples will be from subjects having non-Caucasian ethnicity. The statistical analysis of the data will commence before June 2004 but will not be completed until September as indicated in the original proposal.

EXPENDITURE

The funds expended for the period from July 2003 to the end of February 2004 are set out in the table below:

| Expense Category | Amount Approved | Amount Spent |
|------------------------------|-----------------|--------------|
| Salary, scientific personnel | \$50,000 | \$21,000* |
| Salary, technical personnel | \$61,000 | \$30,000 |
| Consumables | \$120,628 | \$99,000 |
| Overheads | \$30,500 | \$27,000 |
| Totals | \$262,128 | \$177,000 |

* There have been major savings in the professional staff salaries this year because the person carrying out the CIR aspect of the project is now a full time Ph.D. student with a scholarship provided by the University of Sydney. Major aspects of the ketosteroid CIR work form part of his research.

Proposal for Year 2

The original proposal was for a two-year program with the major expenditure occurring in the first year. In the second year the EPO glycoform project will be completed within the first four months and will involve statistical of the data and preparation of a scientific paper summarising the work and its major findings. The CIR measurements will continue but the methodology used will change. The ketosteroid analysis will be essentially complete and the analysis of steroidal diols will begin. The ketosteroid analysis is much simpler than the diol analysis but in some cases of doping with endogenous steroids the diol methodology is the only one that will give a definitive result. We had hoped to develop a simple method for diol extraction and purification prior to GC-CIRMS analysis such as we have done for the ketosteroids, but it appears at this stage that an extensive cleanup using HPLC will be required. Because of this the number of samples that can be analysed using the resources available will need to be reduced from the 1000 stated in the original budget. On current estimates the number of samples that can be analysed will be approximately 500. The samples to be analysed will be chosen from the EPO2000 samples using the data already obtained from the ketosteroid analyses with a view to optimising the subject diversity and hence the statistical significance of the data obtained.

The major objectives for Year 2 are –

- Complete the statistical analysis of the EPO glycoform results and prepare a publication on the results of this study.
- Complete the statistical analysis of the ketosteroid GC-CIRMS measurements and prepare a publication on the results of this study.
- Begin the analysis of steroidal diols using GC-CIRMS with the view to having a statistically significant dataset completed by mid 2005.

Analysis of quantization error in high-precision continuous-flow isotope ratio mass spectrometry

Gavin L. Sacks, Christopher J. Wolyniak, J. Thomas Brenna*

Savage Hall, Division of Nutritional Sciences, Cornell University, Ithaca, NY 14853, USA

Received 10 June 2003; received in revised form 8 August 2003; accepted 12 August 2003

Abstract

High-precision isotope ratio mass spectrometry (IRMS) systems are equipped with digitizers that deliver effective maximum digitization depths of 16 to 24 bits; however, there are no analyses of the proper board depth required to retain high precision in continuous-flow techniques. We report an experimental and theoretical evaluation of quantization error in continuous-flow IRMS (CF-IRMS). CO₂ samples (100 pmol–30 nmol) were injected into a gas chromatography combustion IRMS system (GC-CIRMS). The analog signal was digitized by high precision, 24-bit ADC boards at 10 Hz, and was post-processed to simulate 12, 14, and 16-bit data sets. $\delta^{13}\text{C}_{\text{pdb}}$ values were calculated for all data sets by the conventional “summation” method or by curve-fitting the chromatographic peaks to the exponentially modified Gaussian (EMG) function. Benchmarks of S.D.($\delta^{13}\text{C}_{\text{pdb}}$) = 0.3, 0.6, and 1.0‰ were considered to assess precision. In the presence of significant quantization noise, curve-fitting required several-fold less CO₂ than the summation method to reach a given benchmark. We derived an equation to describe the theoretical limitations of precision for the summation method as a function of CO₂ admitted to the source and the step size of the boards. Theory was in close agreement with the observed lower limit of precision for the simulated 16-bit data set. Curve-fitting achieved a precision of S.D. <0.3‰ for injections 20-fold smaller than summation for CO₂ samples collected on an IRMS with 16-bit resolution. By mitigating the impact of quantization noise, curve-fitting expands the dynamic range within a single run to include lower analyte levels, and effectively reduces the need for high pumping capacities and high precision ADC boards.

1. Introduction

Isotope ratio mass spectrometry (IRMS) coupled to a gas chromatography–combustion interface (GC-C) can routinely measure relative differences in $^{13}\text{C}/^{12}\text{C}$ isotope ratios to a precision of few parts per million for samples containing 10 ng of sample or less

[1,2]. GC-CIRMS data consists of three concurrent chromatographic traces ($^{44}\text{CO}_2$, $^{45}\text{CO}_2$, $^{46}\text{CO}_2$) from three detectors operated in parallel. Achieving high precision requires careful and consistent definition of background levels and peak integration for all three traces. Most commonly, peak areas are integrated by the “summation” method. The start and end of a peak are detected, and the background is described as a square or trapezoidal area beneath the peak. Raw data are summed over the length of the peak, and the background area is subtracted. Ricci et al. [3] described two

E-mail address: jtb4@cornell.edu (J.T. Brenna).

general methods for determining the background using summation; the “individual summation” method, in which the background is defined by connecting low points on either side of the peak, and the “dynamic summation” method, in which low points are connected throughout the chromatogram regardless of the location of peaks.

All IRMS instruments use digitizers to convert analog signal from Faraday cups to digital data, which must be processed to yield isotope ratios. The precision of a digitizer is expressed in terms of bits, where an N -bit board has 2^N steps over a given range. As an example, a 16-bit board has ~65 000 steps; if the board has a range of 0–10 V, then the step size of the board is ~0.15 mV. The rounding of a continuous signal to discrete steps introduces noise, which is referred to as quantization error or “bit noise”. This effect is shown graphically in Fig. 1, where simulated Gaussian peaks of 24, 16, 14, and 12-bit resolution are presented. At high resolution (24 bits), no quantization noise is noticeable, and the peak appears as a smooth trace. As the resolution decreases, steps become obvious, and the shape of the peak deteriorates. The quality of data reduction in continuous-flow IRMS must depend at least in part on the digitizer depth because the intensity level established for peak start and stop depends on this parameter. As depth decreases, the intensity of

the background is, in general, less well represented by the intensity levels of the peak’s start and stop points. There are no analyses available that establish the relationship between isotope ratio precision and digitization depth.

The effect of digitization depth on precision and accuracy is inextricably linked to data reduction algorithms.

The reproducibility of the summation background correction depends in part on the two points that anchor the background line under the peak; imprecision in the measurement of either point multiplies through the entire length of the background segment connecting the points. In the presence of a simple linear background, a background line is easily drawn between any two points on either side of the peak, as shown in Fig. 2a. Chemical noise due to column bleed or contaminant peaks may cause inaccuracy in defining the background, but such noise is usually correlated in all three traces. This covariance may mitigate the effects of chemical noise on the calculated isotope ratio. However, in the case of quantization error, as shown in Fig. 2b, the magnitude and direction of error is uncorrelated among the three traces, and this then poses a special case. Our previous work has shown that peak integration by curve-fitting improves precision and accuracy in cases of low signal-to-noise [4] and overlapping peaks [5]. Background correction

Fig. 1. A simulation of a Gaussian signal collected by ADCs of various resolutions (24, 16, 14, and 12 bits) and quantization errors. At 24-bit resolution, quantization error is not visible, and the peak appears as a smooth trace. At 16 bits, bit noise is evident primarily at the base of the peak. At 12-bit resolution, the signal is barely recognizable as a Gaussian shape.

Fig. 2. Simulated chromatographic peaks in the presence of a linearly rising background (a) without and (b) with quantization error. In the presence of quantization error, the true background may fall anywhere within the arrows. Without quantization error background is easily and accurately achieved by connecting points on either side of the peak.

in curve-fitting is not constrained to the actual values represented by the discrete digitization levels, and we hypothesized that it may not be as sensitive to quantization error as summation.

Quantization error is typically not dominant in GC–CIRMS when high precision IRMS data acquisition systems use sufficiently deep digitization boards and signals are sufficiently strong. Noise from other sources, such as chemical noise, is greater than the step size of the digitizers. However, quantization error may become important in two specific situations: (a) in data reduction of minor peaks in a chromatogram where there are fewer steps between baseline and peak top, and (b) when low precision digitizers are used, as is common in low cost IRMS instruments designed primarily for measurements of high abundance samples, such as CO_2 in breath tests. In addition, these systems usually have lower pumping capacity, which limits the flow rate that the IRMS source accepts. The lower inlet flow rates result in smaller signals for equivalent analyte abundance via higher split ratios, making quantization error more prominent. In this report, we evaluate quantization error theoretically and experimentally to determine the limiting the precision achieved by the conventional summation algorithm and by curve-fitting.

2. Experimental

2.1. Instrumentation

A Varian 3400 GC system was coupled via a combustion furnace to one of two gas IRMS instruments:

(a) a FinniganMAT 252 (FMAT252) run in high linearity mode, or (b) an Analytical Precision Products 2003 (APP2003). Both IRMS systems were operated with a source pressure of 1×10^{-6} Torr and had an absolute sensitivity of ~ 5000 mol/ion (1 Torr = 133.322 Pa). The GC–C system is described in detail elsewhere [6]. Briefly, the effluent from the capillary column (60 m \times 0.32 mm, 0.25 μm , BPX70; SGE, Austin, TX, USA) is directed to a combustion furnace filled with CuO and held at 850 $^\circ\text{C}$, and dried in a Nafion water trap before admittance to the IRMS system through an open split. Since CO_2 gas was injected as a sample, the combustion step was not necessary, but was retained in the system to increase the verisimilitude to real GC–CIRMS operating conditions. The FMAT252 has differential pumping and a higher overall pumping capacity, while the APP2003 has only a single turbopump. As a result, the FMAT252 can tolerate higher inlet flow rates. The open split of the FMAT 252 accepted 0.2 ml/min (split ratio = 8.4:1), and the open split of the APP2003 accepted 0.07 ml/min (split ratio = 24:1).

CO_2 (Airgas East, 99.9%) injections were performed by hand consecutively. The split ratio and the injection size were varied to yield between 100 pmol and 30 nmol on column. Four or five replicates were performed for each injection size. The moles of CO_2 in each injection were approximated by assuming ideal gas conditions.

Data was collected on the FMAT 252 using SAXI-CAB [7], a laboratory-built LabVIEW-based [8] data acquisition system employing National Instruments (Austin, TX, USA) 435 \times digitizers yielding

24 bits operating at 10 Hz. Data were collected on the APP2003 using the vendor-supplied 16-bit, 10 Hz data acquisition system. Both systems simultaneously monitored the $m/z = 44$, 45, and 46 cups with >99% duty cycle.

2.2. Data processing

Before data reduction, data collected from the FMAT 252 at 24 bits was rounded on all three traces to simulate 16-, 14-, and 12-bit data sets. The head amplifiers have a maximum signal of 10 V (33 nA for $m/z = 44$), so the step size, Δ , for a given board depth was calculated as:

$$\Delta = \frac{10 \text{ V}}{2^{\text{bits}}} \quad (1)$$

We created simulated data sets by rounding data points to the nearest step:

$$\text{data(quantized)} = \text{round} \left[\frac{\text{data(raw)}}{\Delta} \right] \Delta \quad (2)$$

where, the *round* function rounds the input to the nearest whole number.

The 16-bit data from the APP2003 was used without modification. All data sets were processed using SAXICAB by either the individual summation method or by curve-fitting. The individual summation method used by SAXICAB was adapted from Ricci et al. [3]. Starts and stops of peaks were determined with a slope sensitivity of 0.3 nA/s. The lowest point 2 s before and 2 s after the peak limits were located, and a straight line was drawn between the two points to define the background. In the curve-fitting algorithm, the traces were fit to exponentially modified Gaussian (EMG) functions using the Levenberg–Marquardt algorithm. Mathematical details of the EMG function can be found elsewhere [9].

High-precision isotope ratios are expressed in the delta (‰) notation:

$$\delta^{13}\text{C}_{\text{pdb}} = \frac{{}^{13}\text{R}_{\text{spl}} - {}^{13}\text{R}_{\text{pdb}}}{{}^{13}\text{R}_{\text{pdb}}} \times 1000 \quad (3)$$

where ${}^{13}\text{R}_x$ is the ratio of ${}^{13}\text{C}$ to ${}^{12}\text{C}$, SPL refers to the sample, and PDB refers to the international standard, Pee Dee Belemnite, where ${}^{13}\text{R}_{\text{pdb}} = 0.0112372$. In our work, $\delta^{13}\text{C}$ of the CO_2 injections were calculated using pulses of standard CO_2 gas that had been indirectly

calibrated to the PDB reference. The contribution of ${}^{17}\text{O}$ to the ${}^{45}\text{CO}_2$ signal was taken into account by the method of Santrock et al. [10]. No outliers were excluded from the reported data.

3. Results and discussion

3.1. Observed effects of quantization error

Fifteen CO_2 injection amounts were used to produce peak areas on the FMAT 252 that varied over 2.5 orders of magnitude. The peaks showed excellent symmetry and narrow peak widths, with a full width at half maximum of <3 s. The mean reproducibility of the area for each injection size, as measured by the area of the $m/z = 44$ signal, was R.S.D. = 13%. Plots of $\delta^{13}\text{C}_{\text{pdb}}$ versus injection size, shown in Fig. 3, are displayed for both the curve-fitting (a) and individual summation (b) methods. The plots are similar in appearance to those presented by others [11] investigating the performance of GC–CIRMS at low signal levels.

In agreement with our previous work [4], we observe modest improvement of precision at low signal levels using the curve-fitting method. Using the summation method, precision deteriorates (S.D. > 1.0‰) for injection sizes less than 400 pmol on column (~50 pmol to the IRMS). Curve-fitting improves this limit to 175 pmol on column (~20 pmol to the IRMS). The integration methods performed comparably and acceptably at large injection sizes. For on-column injections of at least 6.8 nmol (~800 pmol to the IRMS), the individual summation method had a precision of S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) = 0.1‰. The curve-fitting method gave slightly worse precision for large injections, S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) = 0.2‰. It is not obvious why the summation method out-performs the curve-fitting method for very large sample sizes. One possibility is that the precision of the curve-fitting method is limited by differences between the shape of the model EMG function and the shape of real, chromatographic peaks. In this case, increasing the injection size past a certain point would not improve the fit, even though S/N is increasing. Using a different function to describe the peaks may further improve results.

To assess the tolerance of the two integration methods to quantization noise, we evaluated simulated

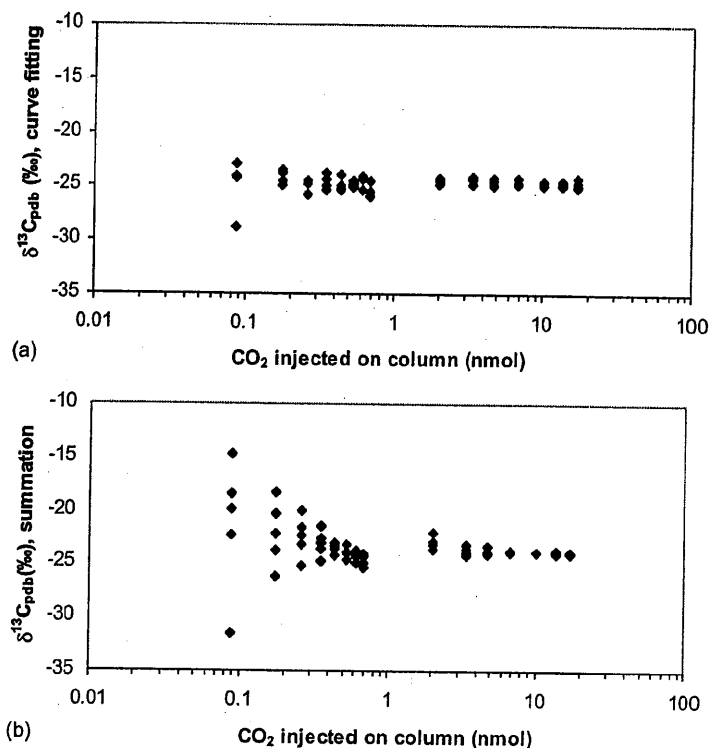

Fig. 3. $\delta^{13}\text{C}_{\text{pdb}}$ vs. CO_2 injected on column for (a) curve-fitting and (b) individual summation algorithms. Data was collected using a homebuilt system at 24 bits from FMAT252.

12, 14, and 16-bit raw data sets generated from the raw 24-bit FMAT252 data, and processed both by curve-fitting and summation. The accuracy of successive injections was very good, even in the presence of bit noise. For each method, the mean $\delta^{13}\text{C}$ for any two injection sizes did not differ significantly. Plots of $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}})$ versus CO_2 injected on column at all bit resolutions are shown in Fig. 4. Each plot appears to extend asymptotically along the x - and y -axes, and we can evaluate the dependence of precision on quantization error visually; poor performance is indicated by the asymptotic plot moving up and away from the axes. At 24-bit resolution, plots of the summation and curve-fitting methods nearly overlap, except at very small injection amounts, indicating that performance is similar. With increasing quantization error, the minimum amount of CO_2 necessary to reach a given level of precision increases rapidly for the summation method. Curve-fitting is more forgiving; precision from 14- and 16-bit data is comparable to

the 24-bit data. The plot for 12-bit resolution shows some loss of precision, but does not fare as badly as the summation method.

To evaluate the methods objectively, we defined $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}}) = 0.3, 0.6$ and 1.0% as benchmarks for high precision. The data were least-squares fitted to a power function, of the form:

$$\text{S.D.} = A[\text{CO}_2]^B \quad (4)$$

where $[\text{CO}_2]$ is the moles of CO_2 injected on column, S.D. is the observed precision, and A and B are constants. The power function was chosen for empirical reasons, because it modeled the observed data acceptably, and the fitted curves can then be compared. The best-fit lines for both the summation (dashed) and curve-fitting (solid) methods are shown in Fig. 4. From the best-fit equations, we calculated the amount of CO_2 injected on-column necessary to achieve the 0.3, 0.6, and 1.0% benchmarks (Fig. 5). With least quantization error (24-bit resolution), the

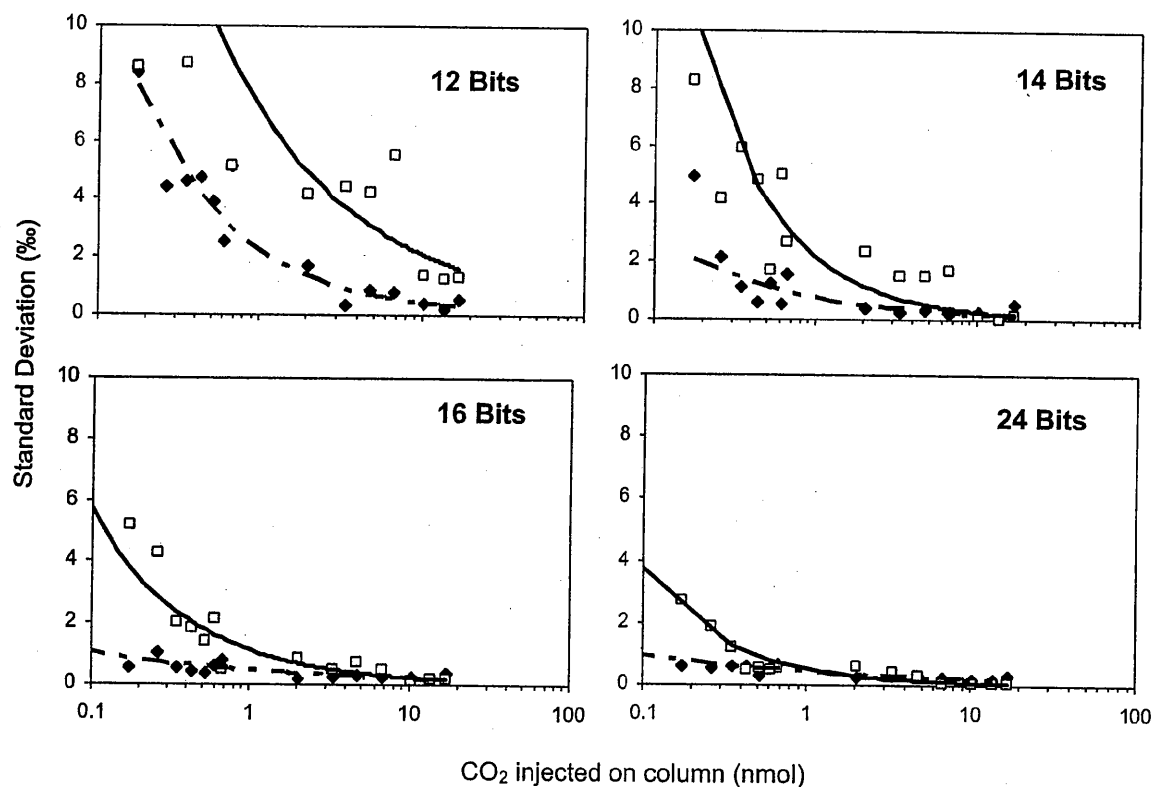

Fig. 4. S.D.($\delta^{13}\text{C}_{\text{pdb}}$) vs. CO₂ injected on column at 12-, 14-, 16-, and 24-bit resolutions, calculated by summation (\square) or curve-fitting (\blacklozenge) algorithms. Each point represents four or five replicates. The data for each method and each resolution was fit to a power equation (general form: $\text{S.D.} = A[\text{CO}_2]^B$, and the best-fit lines are drawn for both methods (solid line: summation; dashed line: curve-fitting).

Fig. 5. Carbon required on-column, in nanomoles, to reach a specified level of precision for a given ADC board resolution. Results are shown for data reduced by curve-fitting and summation algorithms.

summation method requires slightly less CO₂ than the curve-fitting method at the 0.3‰ benchmark (1.86 nmol versus 3.19 nmol). At 16-bit resolution, the summation method requires 6.83 nmol, an increase of 267%, compared to a 25% increase for curve-fitting over the same interval. To reach the 0.6‰ benchmark at 16 bits, summation requires an increase of 224% (from 0.77 to 2.50 nmol), compared to 33% for curve-fitting. At 12-bit resolution, the amount of CO₂ on column necessary to achieve S.D. = 0.6‰ by summation is 107 nmol, which far exceeds the capacity of the GC column. Curve-fitting requires only 6 nmol to reach S.D. = 0.6‰ at 12-bit resolution. As was discussed previously, curve-fitting is superior to summation at the 1.0‰ benchmark, even in the absence of quantization noise. At 24 bits, curve-fitting requires 80 pmol to achieve S.D. = 1.0‰, five-fold less than summation; a similar level of improvement in precision is seen at 14- and 16-bit resolution.

To summarize, in the absence of quantization noise, similar amounts of CO₂ are necessary to achieve precision of 0.3–0.6‰ for both integration methods. The summation method requires a dramatic increase in the injection size to maintain this level of precision in the presence of quantization noise, while the curve-fitting method is relatively unaffected. At a lower standard of precision (S.D. = 1.0‰), curve-fitting is superior regardless of the magnitude of quantization error.

3.2. Theoretical limits of quantization error on precision

In IRMS, the signal is recorded as a voltage proportional to the ion current, and can be reported in amperes or in volts. If the signal is reported in volts, the area of the $m/z = 44$ signal, A_{44} , is related to the moles of ⁴⁴CO₂ that enters the IRMS, [⁴⁴CO₂], by the equation:

$$A_{44} = [\text{}^{44}\text{CO}_2] \frac{N_a e}{E} R_\Omega \quad (5)$$

where N_a is Avogadro's number, e is the fundamental charge, E is the absolute sensitivity of the IRMS in molecules/ion, and R_Ω is the feedback resistance of the amplifier.

In the summation method, the background is defined by drawing a line between two background points, (t_1, y_1) and (t_2, y_2) ; the background area, A , is the

trapezoidal region between this line and the time axis. We can calculate this area by the equation:

$$A(\text{background}) = \frac{1}{2} W(y_1 + y_2), \quad (6)$$

where $W = t_2 - t_1$

Quantization noise is uniformly distributed over an interval and the error for a single measurement is:

$$\sigma_y = \frac{\Delta}{\sqrt{12}} \quad (7)$$

where Δ is the minimum step size of the acquisition boards. A full derivation of this can be found in Haykin's text on digital communication [12]. Assuming that quantization error at y_1 and y_2 is uncorrelated, we can use standard techniques for propagation of errors to determine the total quantization error in measuring the background area, σ_A :

$$\sigma_A = \frac{W\Delta}{2\sqrt{6}} \quad (8)$$

It has been noted that evaluating the effect of chemical noise on precision of isotope ratios is difficult, because this noise is usually highly correlated between the major and minor traces [11]. Unlike chemical noise, quantization noise on each trace should be uncorrelated. This greatly simplifies calculation of the propagation of errors for the relation of the observed isotope ratio, ⁴⁵ R_{obs} , to the actual isotope ratio, ⁴⁵ R_{act} :

$${}^{45}R_{\text{obs}} = \frac{A_{45} \pm \sigma_{45}}{A_{44} \pm \sigma_{44}} = {}^{45}R_{\text{act}} \pm \sigma_{\text{obs}} \quad (9)$$

where

$$\sigma_{\text{obs}} = {}^{45}R_{\text{act}} \sqrt{\left(\frac{\sigma_{45}}{A_{45}}\right)^2 + \left(\frac{\sigma_{44}}{A_{44}}\right)^2} \quad (10)$$

The standard error can be rearranged and expressed in terms of parts per thousand:

$$\begin{aligned} \sigma_{\text{ppt}} &= 1000 \times \frac{\sigma_{\text{obs}}}{{}^{45}R_{\text{act}}} \\ &= 1000 \times \sqrt{\left(\frac{\sigma_{45}}{A_{45}}\right)^2 + \left(\frac{\sigma_{44}}{A_{44}}\right)^2} \end{aligned} \quad (11)$$

At natural abundance, $A_{45} \sim 0.011A_{44}$. Assuming the feedback resistance is 100× larger for the 45 cup than for the 44 cup, $\Delta_{45} = 0.01\Delta_{44}$. Combining this and Eqs. (5), (8) and (11), we arrive at:

$$\sigma_{\text{ppt}} = \frac{276W\Delta_{44}E}{[\text{}^{44}\text{CO}_2]N_a e R_\Omega} \quad (12)$$

Fig. 6. S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) vs. CO_2 injected on column for simulated 16-bit data. The line indicates the theoretical limit of precision as a function of injection size, as calculated from Eq. (12).

At natural abundance, a standard deviation of $\sigma_{\text{ppt}} = 1.0$ is approximately equivalent to $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}}) = 1.0\%$. We used Eq. (12) to predict the standard deviation as a function of injection size at 16-bit resolution, compensating for an open split ratio of 8.4:1. The integration window, W , was assumed to be constant at 10 s, $E = 5000$, and $R_{\Omega} = 3 \times 10^8 \Omega$. A plot of the calculated limits compared to the observed precision at 16 bits is shown in Fig. 6. There is good agreement between theory and experiment. The calculated precision is within a factor of five of the observed precision for all injection sizes. More striking, the calculated precision is a “lower limit”, as nearly all the measured precisions lie above the theoretical prediction. The biggest discrepancies occur for large injection sizes, where the effect of quantization error is minimized, and other sources of error (e.g. contaminants) may dominate.

Eq. (12) can also be used to demonstrate that quantization error should be negligible for signals acquired with 24-bit digitizers. Eq. (12) predicts that only 0.6 pmol of CO_2 to the IRMS should be necessary to achieve a precision of 0.5% if quantization error is the only limiting factor. However, counting statistics dictate that a minimum number of ions must be formed to achieve a specified precision to overcome the shot-noise limit. Merritt and Hayes [11] give this equation as:

$$\sigma_{\delta}^2 = \frac{(2 \times 10^6)(1 + R)^2}{EmN_a R} \quad (13)$$

where σ_{δ} is the shot noise limited standard deviation, R is the natural abundance isotope ratio, E is the ionization efficiency, m is the moles of CO_2 , and N_a is Avogadro's number. Substituting $E = 5000$ and $R = 0.011$, we find that 6 pmol of analyte is required to achieve $\text{S.D.} < 0.5\%$. Therefore, when high precision 24-bit boards are used, the effect of quantization error is superseded by shot noise.

Our theoretical treatment gives insight into why curve-fitting is less sensitive to quantization error than summation. In the summation methods we have discussed, imprecision in a single data point chosen as the background is multiplied throughout the background correction; for a peak width of N data points, the total quantization error scales as N . In contrast, the algorithms used in curve-fitting minimize the sum of squares between the fit curve and every data point. In curve-fitting, the quantization noise for each individual point is averaged over the entire curve; for N data points, the total quantization error scales as $N^{1/2}$. For a peak width of 10 s and a sampling rate of 10 Hz, this translates into a 10-fold reduction of quantization error.

The theoretical treatment we describe is appropriate for understanding the effects of quantization error on summation integration methods that choose single points on either side of the peak to define a background. It does not examine the limits of other classes of data reduction methods. An obvious improvement to the summation integration method would be to average n points on either side of the peak, which would increase the effective number of bits of

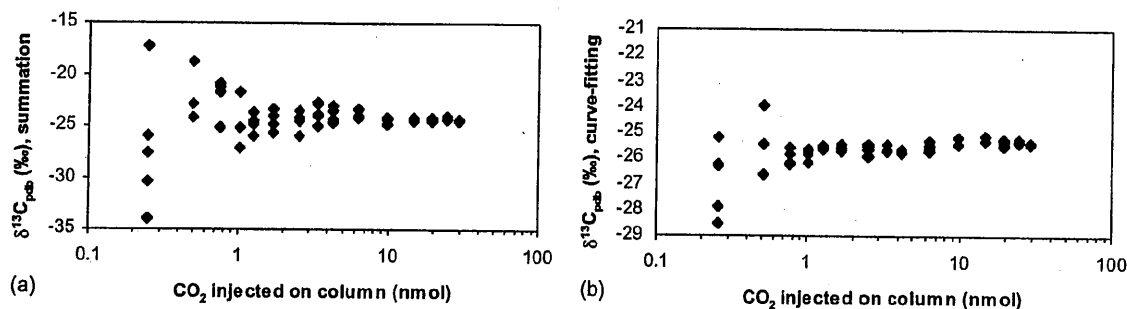

Fig. 7. $\delta^{13}\text{C}_{\text{pdb}}$ vs. CO_2 injected on column for (a) individual summation and (b) curve-fitting algorithms. Data was collected at 16 bits and 10 Hz on the APP2003.

the background measurement by $n^{1/2}$. While this approach could work well for isothermal runs with constant background, it is much less suitable for complex GC–CIRMS chromatograms, where it is not obvious which points should be averaged; that is, which points represent pure background and do not contain chemical noise or the tail ends of peaks. Ricci et al., observed that the averaging method gives slightly higher background values than other corrections [3]. They also reported that the dynamic background correction (which uses single points) yielded improved δ -values over the averaging method. Thus, a method may be insensitive to quantization error, but may still give worse results due to other variables.

3.3. Improving precision on a 16-bit IRMS

To test the effectiveness of curve-fitting on GC–CIRMS data acquired by low precision digitiz-

ers, we ran multiple CO_2 injections on an APP2003 using 16-bit digitizers, and otherwise in similar fashion to the work on the FMAT252. A plot of $\delta^{13}\text{C}_{\text{pdb}}$ versus injection size is shown for summation (Fig. 7a) and curve-fitting (Fig. 7b). Fig. 8 shows a plot of S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) as a function of injection size for both integration methods. The theoretical limit on the summation method, calculated from Eq. (12), is shown in the same figure as a dashed line. The observed precision for the summation method agrees well with theoretical predictions; most of the data points lie just above the lower limit curve. Almost 15 nmol of CO_2 on column are necessary to achieve a precision of $<0.3\%$ using the summation method. Using curve-fitting, only 0.76 nmol are necessary to reach that level of precision, a 20-fold improvement. This is greater than the two-fold advantage seen by curve-fitting the 16-bit data from the FMAT 252. One possible explanation is that the APP2003 data is

Fig. 8. S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) vs. CO_2 injected on column for runs on APP2003 with 16-bit boards. The dashed line indicates the theoretical limit of quantization error on precision as a function of injection size, as calculated from Eq. (12).

affected primarily by bit noise, while the FMAT252 data has other sources of noise that cannot be eliminated by curve-fitting. The FMAT252 accepts a three-fold higher flow rate than the APP2003, so there is likely more chemical noise in the FMAT252 signal.

The relative immunity to quantization error with curve-fitting permits the IRMS to be run at lower inlet flow rates, which effectively increases quantization noise by decreasing the number of steps between background and peak with relatively little influence on chemical noise. The advantages of lower inlet flow rates are a longer lifetime for the filament, and reduced need for pumps and pumping capacity. These benefits, plus the reduced need for expensive ADC boards, should make high-precision GC–CIRMS more amenable to portable and low-cost applications. In principle, statistical considerations define the lower limits of flow rates. However, counting statistics dictate that S.D. = 0.5% requires 6 pmol of CO₂ to the source for a typical continuous flow IRMS ($E = 5000$), and GC–CIRMS applications usually work well above this limit. Thus, modestly lower resolution and inlet flow rates should not significantly affect performance, so long as appropriate integration techniques are used.

4. Conclusions

Data reduction using curve-fitting is more robust than the conventional summation method in the presence of even modest levels of quantization error. Using data obtained on high precision digitizers, the curve-fitting algorithm required several-fold less CO₂ to reach benchmarks of high precision (S.D. = 0.3, 0.6, and 1.0%) at any of the three simulated board depths (12, 14, or 16 bits). The poor performance of the summation algorithm was particularly noticeable at the 12-bit resolution, where S.D. < 1.0% could not be reached even at the maximum injection size allowed by the dynamic range of the Faraday cups. We

have derived an expression that describes the influence of quantization noise on isotope ratios calculated from raw IRMS data, and shown that it accurately predicts the lower limit of precision. Our theoretical treatment assumes that quantization error is uncorrelated between the $m/z = 44$ and 45 signals, and is appropriate for any data reduction algorithm that uses single points on either side of the peak to describe the background.

Curve-fitting substantially improved precision on GC–CIRMS data collected by an instrument with 16-bit digitizers. The summation algorithm required 15 nmol of CO₂ on-column to achieve a precision of S.D. = 0.3%, while curve-fitting required only 0.76 nmol. Thus, IRMS with 16-bit ADC boards achieved high precision for less than 1 nmol of C on column, a common benchmark for GC–CIRMS applications, despite using 16-bit ADC boards. Lower inlet flow rates, enabling reduced pumping requirements, may be an important advantage in some applications.

14 High-Precision Measurement of $^{13}\text{C}/^{12}\text{C}$ Ratios by On-Line Combustion of GC Eluates and Isotope Ratio Mass Spectrometry

M. RAUTENSCHLEIN, K. HABFAST AND W. BRAND

Finnigan MAT GmbH, Barkhausenstrasse 2, D-2800 Bremen, FRG

Introduction

The stable isotopes of carbon (^{12}C , ^{13}C) are widely used in natural sciences: in geology, by measuring isotope ratios; in organic compounds, or in human studies, by using artificially enriched compounds as tracers.

First, the natural variations of the $^{13}\text{C}/^{12}\text{C}$ ratio are studied by means of isotope ratio mass spectrometry (IRMS). Various processes fractionate the carbon isotopes in nature. The observed isotope ratios provide information on these processes, for example on palaeotemperatures or on specific chemical or biological reactions; or they can be used, for instance, to trace the origin and/or genesis of a specific compound.

Secondly, the isotopic content of ^{13}C in samples artificially enriched with ^{13}C -labelled components is measured, usually with combined gas chromatography/mass spectrometry (GC/MS). This replaces ^{14}C labelling and thus avoids any radiation hazards. This method is used preferentially in biology, biochemistry or clinical and environmental research, where medical ethics discourage the use of radioactive tracers for investigative purposes.

In both application areas very small amounts of ^{13}C must be detected. On the one hand, significant natural variations in the approximately 1.1% ^{13}C abundance (in relation to ^{12}C) are as small as 0.0002 atom%. Hence, small natural variations in the amount of ^{13}C must be detected in the presence of 100 times more ^{12}C . This requires very high precision in measuring the $^{13}\text{C}/^{12}\text{C}$ ratio, as is normal with IRMS.

On the other hand, in labelling studies, normally only very small amounts of sample are available and the compounds are separated on line in the GC/MS. Hence, the capability for detecting small amounts of ^{13}C is mandatory. From an analytical point of view, this is totally equivalent to the requirement for high

Stable Isotopes in Paediatric Nutritional and Metabolic Research
© Intercept Ltd, PO Box 716, Andover, Hampshire, SP10 1YG, UK

precision in the $^{13}\text{C}/^{12}\text{C}$ natural ratio determination in IRMS as only low amounts of ^{13}C -labelled material are present.

The type of compound (organic, inorganic, solid, liquid, gaseous) that must be handled by these mass spectrometric methods is very diverse. No mass spectrometer, IRMS or GC/MS is able to accept such a broad variety of sample types directly for an isotope ratio determination. In $^{13}\text{C}/^{12}\text{C}$ isotope ratio mass spectrometry each isolated compound of interest is combusted to CO_2 then measured. This greatly simplifies the mass spectrometer and offers two definite advantages towards the achievement of high precision and accuracy: the isotope ratio can always be measured by one and the same sample triple collector, adjusted for the simultaneous recording of masses 44 ($^{12}\text{C}^{16}\text{O}_2$), 45 ($^{13}\text{C}^{16}\text{O}_2$) and 46 ($^{12}\text{C}^{18}\text{O}^{16}\text{O}$) and one can always use the same inexpensive working standard gas (CO_2) to calibrate the mass spectrometer easily at short time-intervals.

This elegant methodological simplicity in IRMS is counterbalanced by the apparent need of a variety of sample preparation and isolation methods, which are more or less specially adapted to certain compound types. Such methods range from rather special ones, e.g. the reaction of carbonates with phosphoric acid to yield CO_2 , to more universally applicable processes, such as the catalytic combustion of all kinds of organic compounds. If the isotope ratio of one or of all compounds in a mixture is requested, a separation process (e.g. a gas chromatographic separation) is required before the conversion to CO_2 .

For all of these methods, there is one common requirement: they must separate and then convert the sample into CO_2 so that the isotope ratio of each sample is preserved in the CO_2 measured by IRMS. Apparently, this requirement is the critical step of the whole method.

Classical isotope ratio mass spectrometers use a dual gas-inlet system, where one sample container is used to store the sample CO_2 and the other one to store the working standard gas. Sample and standard, both pure CO_2 , are repeatedly introduced intermittently at 4–8 seconds' time-intervals into the mass spectrometer and are directly compared to each other.

By this (batch-) type of sample to standard comparison method, the highest possible precision and accuracy is achieved. However, the method is totally incompatible to modern types of continuous-flow separation, such as gas chromatography or combustion devices, which normally use a carrier gas like helium and which make each sample available for measurement as a 'peak' for a few seconds only.

This incompatibility led to the (recent) development of the non-classical continuous-flow introduction method, which will be described in more detail below. We call this method in its combination with a gas chromatograph, 'GC combustion isotope ratio mass spectrometry (GC/C/IRMS)'.

Experimental set-up of GC/C/IRMS

Figure 14.1 shows the schematic layout of our complete system: a capillary gas chromatograph is coupled on-line to a triple collector (masses 44/45/46) isotope ratio mass spectrometer via a combustion interface. A second, switchable gas inlet

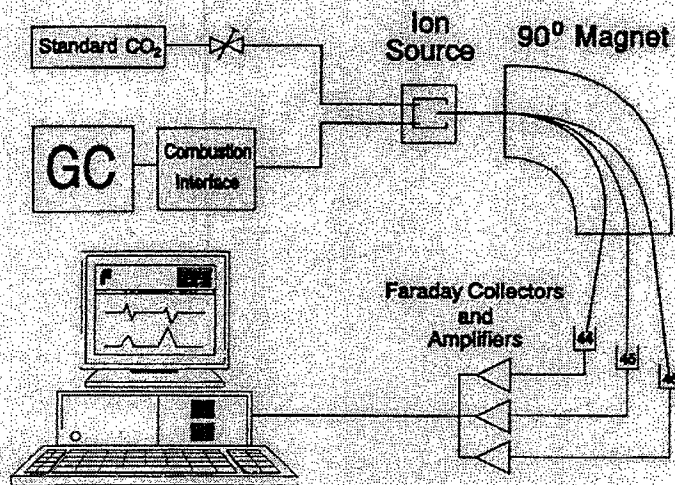

Figure 14.1 Schematic layout of the GC/C/IRMS (gas chromatograph/combustion/isotope ratio mass spectrometer) system.

line to the mass spectrometer is used to introduce a standard gas (CO_2). The mass spectrometric data are acquired and evaluated by a PC-based data system using a multitasking operating system with a graphic, menu-operated user interface.

In Figure 14.2, the combustion interface is shown in more detail. A capillary gas chromatographic column is connected to a high-efficiency microcombustion furnace via a post-column splitter. The second outlet of the splitter can be

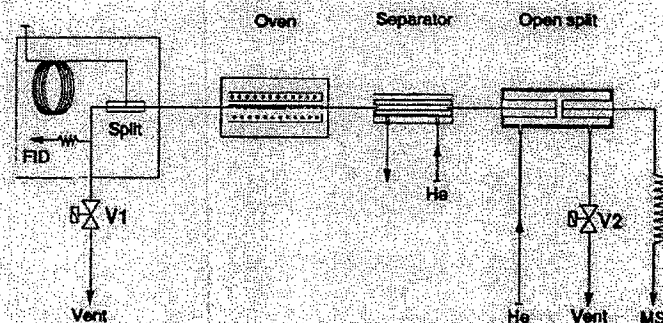

Figure 14.2 Combustion interface of the GC/C/IRMS system.

connected to any type of GC detector (flame ionization detector (FID), thermal conductivity detector (TCD) or ion trap detector/mass spectrometer (ITD/MS)) and is connected in parallel to a high-conductivity vent, which can be closed by valve V1.

The combustion furnace consists of a quartz capillary at 820°C, filled with platinum and copper oxide, serving as a combustion catalyst and as a source of oxygen. Behind the furnace, a capillary-shaped phase separator, made of selectively permeable membrane materials, is connected. This simple dead-space-free device removes all water from the mixture of combustion products. A conventional open split couples the combustion system to the mass spectrometer via a capillary, which limits the flow to 0.6 ml min⁻¹, practically independent of the flow conditions in the rest of the system. The open split is fed with a constant flow of make-up gas (He) which can leave the split device via valve V2.

The chromatographic resolution of the complete, virtually dead-space-free

Figure 14.3 Detail of a combusted crude oil chromatogram: recording of the $^{13}\text{C}^{18}\text{O}_2^+$ ion current, m/z 44.

combustion system can be judged from Figure 14.3, which shows part of the mass 44 recording trace of a mixture of hydrocarbons.

Depending on the status of the two valves V1 and V2 (Figure 14.2), the combustion system operates in two different modes. First, during normal operation, when the GC eluates are to be combusted, V1 is closed and V2 is open. Thus, because of the closure of the high conductivity vent, the post-column split feeds the majority of the gas flow through the combustion system and only a small portion is flowing to the GC FID detector.

Secondly, in order to prevent the solvent, or any other undesirable eluate (which would possibly destroy the furnace's catalytic activity), from entering the combus-

tion system, V1 is opened and V2 is closed. In this way, the flow through the system is reversed by the open split's make-up gas, and all GC eluates are now completely directed to vent via the post-column split. The flow to the GC detector is still maintained, as well as the pure helium flow to the mass spectrometer.

For illustrative simplicity, another feature of the combustion system is not shown in *Figure 14.2*: oxygen can be introduced into the furnace to regenerate the copper oxide that is slowly used by the combustion process.

In order to cope with the relatively high helium flow, the mass spectrometer itself is differentially pumped. For the same reason the gas conductance of the ion source is raised to approximately 1.6 l s^{-1} (air), which results in approximately half the ion-source sensitivity as compared to the normal operation of an isotope ratio mass spectrometer (without helium flow): for 1 nmol of CO_2 introduced into the ion source, one detects about 8×10^{10} ions at the mass 44 collector.

For the measurement of an isotope ratio of 1 : 100, the statistical limit allows a best relative precision of approximately 5×10^{-3} for one nmol of CO_2 . In the Faraday cup recording system, the rise time of the DC amplifiers for the three ion collectors is carefully matched to an appropriate value [200 milliseconds (ms)], although they use working resistors which differ by more than a factor of 100 (because of the different abundances of the three ion currents). The ion current signals are integrated for selectable time-intervals (range 60–500 ms). Hence, at least 20 triple-collector readings can be taken for a 5 s GC peak.

Typical ion current (m/z 44) and isotopic ratio (m/z 45 : m/z 44) chromatograms are shown in *Figure 14.4*. The lower graph shows the intensity recording of the mass 44 ($^{12}\text{CO}_2$) trace, and is very similar to a direct FID trace of the gas chromatograph or a total ion current recording chromatogram of a conventional GC/MS system. The upper graph shows the plot of the ratios of the traces of masses 45 and 44 as a function of time. The scale is calibrated in δ -values, i.e. the relative difference of the measured ratio (in Pee Dee belemnite limestone) given in parts per thousand or per mil (‰). In addition, a total of three standard CO_2 gas injections are shown before and after peak number 4, benzaldehyde (*Figure 14.4*).

The isotope ratio traces of the gas chromatographic peaks exhibit a typical S-shape, whereas the standard gas injections, which are introduced directly into the ion source, show a nearly rectangular ratio response (*Figure 14.4*, upper trace). The reason for the S-shaped isotope ratio (*Figure 14.5*, lower trace) of the GC peak is that the 'heavier' isotopic species of a compound elutes more rapidly from the high-resolution capillary column than the light species (*Figure 14.5*, upper trace). This behaviour is the result of a vapour pressure isotope effect, and is an often observed phenomenon in GC/MS selected ion monitoring. The actual ratio is computed from the ratio of the area under the two isotopic peaks. Hence, care must be taken to integrate in currents across the full width of the chromatographic peaks.

During the run of a gas chromatogram, a real-time plot of the GC trace and of the $^{13}\text{C}/^{12}\text{C}$ ratio is shown on the screen of the computer. Data evaluation is performed fully automatically after the completion of the gas chromatogram. The user can manually change the integration program via a dialogue, if necessary, to advise the system of the proper choice of baseline ratio values.

Figure 14.4 Chromatogram ($^{13}\text{C}/^{12}\text{C}$ ion current, m/z 44) and isotopic ratio (in ‰ notation) of a standard mixture, together with three CO_2 reference gas injections.

Figure 14.5 The origin of the S-shaped ratio output: the heavier isotopic species elutes more rapidly from the capillary column than the lighter (more abundant) ^{12}C species.

Nomenclature and methodology

The 'isotope ratio' (r) of a sample is the ratio of the number (n_i) of two isotopes ($i = 1, 2$):

$$r = \frac{n_2}{n_1}$$

Therefore, the atom% value (a) of the (n_2) isotope is:

$$a = \frac{100 r}{(r + 1)} = \frac{(100 n_2)}{n_1 + n_2}$$

The 'enrichment' of an isotope in a sample as compared to a standard value (a_s) is, therefore, given by atom% excess (APE):

$$\text{APE} = a - a_s$$

An isotope ratio mass spectrometer measures the isotope ratio. The measured raw isotope ratio is, however, influenced by several mass discriminating effects which fluctuate with time and from instrument to instrument. In order to achieve the best precision and the best accuracy, each ratio measurement *must* be calibrated by the measurement of a standard with known isotopic composition. Otherwise, measurements made at different times on the same instrument and other instruments would be incomparable.

This is the basic reason why isotope ratios are always measured and reported relative to a standard value. However, classically with IRMS (and in contrast to the usual way to report the amount of isotopically labelled species in a sample, as with GC/MS) not the 'enrichment' versus a standard, i.e. the value APE (where r_s is the isotope ratio in the standard)

$$\text{APE} = \frac{(r_s - r) 100}{(r + 1)(r_s + 1)}$$

is reported, but the so-called δ -value:

$$\delta = \frac{r}{r_s - 1} \times 1000$$

This is the relative difference of a ratio r from a standard ratio r_s , given in parts per thousand, or per mil (‰).

The relationship between the enrichment and the δ -value is basically non-linear. For all details, how to 'convert' δ -values into atom% or atom% excess values and vice versa, see Figure 14.6.

If the measured isotope ratios are related to a standard near the natural level of ^{13}C (approximately 1.1‰), a linear approximation can be used for δ -values up to approximately $\delta = 1000$ ‰ (i.e. for $r = 2r_s$ or ≈ 1 atom% excess):

$$\text{APE} = \frac{a_s \times \delta}{1000}$$

$$\text{ape}_u = a_s \frac{\delta_u \times (100 - a_s)}{a_s \times \delta_u + 10^5}$$

$$a_u = a_s \frac{(1 + \frac{\delta_u}{1000}) \times 10^5}{a_s \times \delta_u + 10^5}$$

$$\delta_u = \frac{\text{ape}_u \times 10^5}{100 - (1 + \text{ape}_u) \times a_s}$$

$$\delta_u = \frac{(a_u - a_s) \times 10^5}{(100 - a_u) \times a_s}$$

a_u, a_s, ape_u in %

δ in ‰

Figure 14.6 The conversion of atom% values into δ -values and vice versa. a_u , atom% of sample; a_s , atom% of standard; ape_u , atom% excess in sample.

This relationship shows the 'high resolution' of the δ -scale as compared to the atom% scale: a δ -value of 1‰ corresponds to 0.001 atom% excess at natural level (1%).

n-Butanol was used as the internal standard.

For a complete GC run, basically two different ways of standardization are available. First, a dose of CO_2 of known isotopic composition is introduced directly into the ion source (or somewhere into the helium flow of the combustion interface) and the isotopic ratio of all GC peaks is related to this gas. Several standard injections can also be distributed across the whole run, if necessary.

Secondly, one or several compounds with known isotopic composition are used as internal standards in the sample mixture. Besides the proper use of a standard, the selection (or measurement) of the correct baseline values is important. It must be noted that the isotope ratio of the baseline may be different at different times during the GC run, due to a changing column bleed.

Table 14.1 summarizes the repeated measurements of the mixture of standards that was shown in Figure 14.4. *n*-Butanol was used as internal standard for measurement of the isotope ratios. The external standard deviation of these measurements is better than 0.3‰. This means that two samples whose isotopic composition differs by only 0.0003 atom% can be differentiated by this method.

In order to demonstrate the excellent linearity of the method over a wide range of (small) isotopic concentrations, we have measured several precise mixtures of $[1-^{13}\text{C}]$ palmitate diluted with unlabelled palmitate as methyl ester derivatives. Our results are shown in Figure 14.7. The measured δ -values have been converted into atom % excess values, using the isotopic content of the unlabelled palmitate methyl ester as the reference. It should be noted that a range of approximately 7‰ in the δ -value covers almost two orders of magnitude in isotopic concentration of the sample.

Figure 14.7 Calibration graph of a $[1-^{13}\text{C}]$ palmitate methyl ester dilution series. The measured δ -values (\pm SD), shown next to the data points, have been converted into atom % excess values. (Samples courtesy of T.E. Chapman, University Hospital Groningen, The Netherlands.)

In order to check not only the precision, but also the accuracy of our results (i.e. of our standardization procedure), the individual compounds of the test mixture (Figure 14.4) were analysed individually with the classical high-precision total combustion method (Dumas combustion). The mean isotope ratios (and their standard deviations) are shown in Table 14.2, together with the means from the GC combustion run of the mixture. The difference of the isotopic ratios obtained by both methods is smaller than 0.2‰ (δ -notation) in most cases and is, therefore, safely within the statistical uncertainties.

Table 14.2 Comparison of GC/C/IRMS and classical off-line combustion and IRMS isotope analysis of a standard mixture

| Compound | GC/C/IRMS $\delta^{13}\text{C}_{\text{PDB}}$ (‰) mean (\pm SD) | Dual inlet $\delta^{13}\text{C}_{\text{PDB}}$ (‰) mean (\pm SD) | Difference in $\delta^{13}\text{C}$ (‰) |
|------------------------|---|--|--|
| <i>n</i> -Butylacetate | -28.97 (0.23) | -28.78 (0.01) | 0.19 |
| <i>n</i> -Butanol | -23.56 (0.06) | -23.56 (0.06) | (0.00) |

n-Butanol was used as the internal standard in the GC/C/IRMS measurements, its $\delta^{13}\text{C}$ value was measured using off-line combustion and classical IRMS.

The difference in $\delta^{13}\text{C}$ (‰) values between the two techniques was GC/C/IRMS values minus the dual inlet values.

PDB, Pee Dee belemnite limestone.

Application examples

The carbon and hydrogen isotopic ratios of the light hydrocarbons in natural gas are useful indicators for gas and oil deposits. *Figure 14.8* shows a typical recording of the measurement of a natural gas sample, together with two reference CO_2 gas injections at the end of the gas chromatogram. The δ -values range from -32‰ to -25‰, with standard deviations in measurements ranging from 0.2‰ to 0.4‰ ($n = 8$) (*Figure 14.9*).

The *n*-alkanes in crude oil also show differences in isotopic ratios. An example for *n*-alkane up to C_{30} is shown in *Figure 14.10*.

Food flavours are normally mixtures of compounds. For economic reasons, very often such flavours are synthesized artificially instead of being extracted from plants. Synthesized flavour extracts show a different isotopic pattern from their natural counterparts, and this can be used to differentiate between them. One example (strawberry aroma) is given in *Figure 14.11*.

An interesting feature of the GC combustion isotope ratio method is shown in *Figure 14.12*. It shows a gas chromatogram of an extract from a fermentation experiment. At two locations in the chromatogram one can observe a big (non-S-shaped) isotope signal (upper trace) whereas virtually no corresponding peak can be found at m/z 44 (lower trace). This points to a highly ^{13}C -enriched compound (virtually no ^{12}C content) at a very low concentration.

In *Figure 14.13*, we therefore show the enlarged traces of masses 44 and 45: a $^{13}\text{C}^{16}\text{O}_2^+$ trace can be detected (10 mV), a $^{12}\text{C}^{16}\text{O}_2^+$ trace at natural level should be present with about the same intensity, but is, actually, much smaller. This is the

Figure 14.8 Raw data output from a natural gas sample: $^{13}\text{C}^{16}\text{O}_2^+$ ion current, m/z 44, and isotopic ratio (δ -notation).

explanation why the ratio signal does not show the typical S-shape. The isotopic content (corrected for baseline) is 4 atom% excess. The peak height at mass 45 corresponds to 2 pg of ^{13}C label, the signal-to-noise ratio of the ratio peak being better than 100 : 1 (Figure 14.13, upper trace). The 'detection limit' with a signal-to-noise ratio of 10 : 1 would, therefore, be estimated to be 200 fg.

With these few examples we have demonstrated the great potential of this new analytical method. We believe it will find many applications in the future.

Figure 14.9 The isotope ratios of a natural gas sample, relative to Pee Dee belemnite limestone (PDB), the international standard.

ABSTRACT

Eakin, P.A., Fallick, A.E. and Gerc, J., 1992. Some instrumental effects in the determination of stable carbon isotope ratios by gas chromatography–isotope ratio mass spectrometry. In: R.S. Harmon and R.W. Hinton (Guest-Editors), *Frontiers in Isotope Geosciences, Chem. Geol. (Isot. Geosci. Sect.)*, 101: 71–79.

Some sources of instrumental errors in the determination of $^{13}\text{C}/^{12}\text{C}$ in organic compounds by gas chromatography–isotope ratio mass spectrometry (GC–IRMS) have been investigated. For mass 44 ion beam intensities in the range $1 \cdot 10^{-10}$ to $1 \cdot 10^{-8}$ A, mass-spectrometric pressure effects do not significantly affect data accuracy, thus obviating the necessity of matching sample and reference ion beam intensities for each compound in a complex sample. Data quality is influenced by: (a) the quality of the furnace-tube packing; and (b) the performance of the cryogenic trap. On analysis of large (70 ng) samples, precisions (1σ) of $\leq \pm 0.23\%$ were obtained using 0.35–0.5-mm-grade CuO. However, there was a marked deterioration in precision ($1\sigma \leq \pm 0.62$) when coarse CuO (0.35–1 mm grade) was tested. Use of fine CuO also permits analysis of smaller samples. Inefficient trapping, and release of water during overnight defrosting leads to erroneously low $\delta^{13}\text{C}$ -values, accuracies of -1.1 to -0.25% resulting from analysis of 70-ng samples. Accuracy error increases to $\leq 1.86\%$ on analysis of 10-ng samples. Efficient water trapping combined with the improvements in furnace performance results in precisions generally much better than $\pm 0.4\%$ and accuracies better than $\pm 0.65\%$ for high-molecular-weight compounds (268–338 amu), and very accurate and precise results (better than $\pm 0.2\%$) for lower-molecular-weight compounds (142–173 amu).

1. Introduction

The VG Isochrom II[®] gas chromatography–isotope ratio mass spectrometer (GC–IRMS) system allows rapid determination of $\delta^{13}\text{C}$ -values of individual organic compounds in complex mixtures. The method utilises a gas chromatograph to separate the sample into its constituent compounds (Fig. 1a). These compounds elute from the column-end at different times according to their molecular weight and structure.

Correspondence to: P.A. Eakin, Isotope Geology Unit, Scottish Universities Research and Reactor Centre, East Kilbride, G75 0QU, Scotland, UK.

On elution, the compounds are carried in a continuous helium stream through an oxidising furnace containing granules of Cu(II)O (Fig. 1b). The rate of combustion and passage through the furnace is similar for all compounds, thus the separation achieved during chromatography is maintained. H_2O is removed from the oxidation products by means of a cryogenic trap (Fig. 1c). The mixture then passes to a single-inlet, triple-collector isotope ratio mass spectrometer (Fig. 1d). The stable carbon isotope composition of each compound is computed by comparison of the sample 45/44 ratio with that of reference CO_2 (Fig. 2) and normal corrections are applied for the

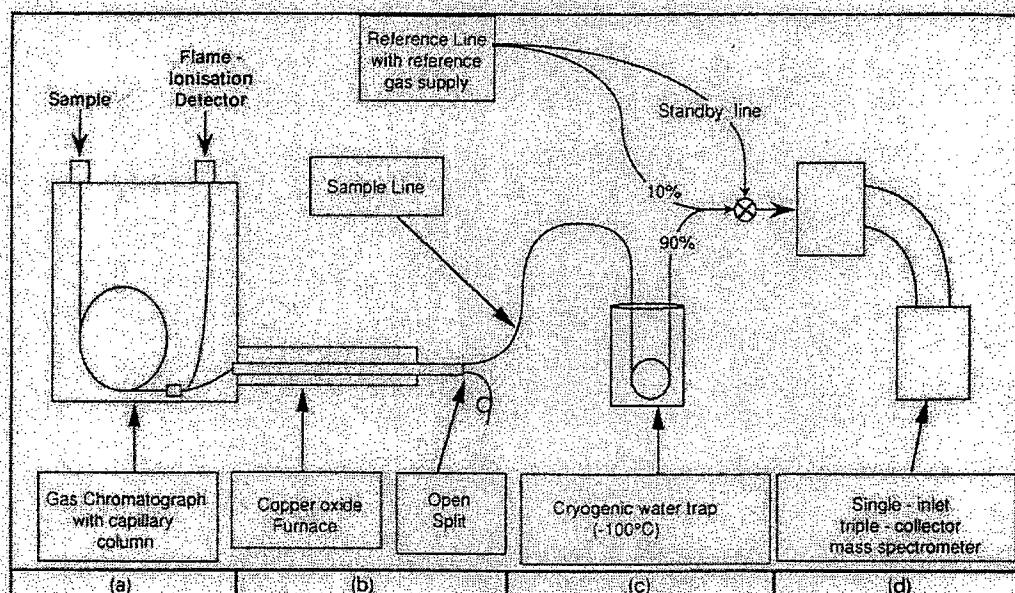

Fig. 1. Schematic representation of the VG Isochrom® GC-IRMS system.

- The gas chromatograph is responsible for separation of the mixture into its constituent compounds.
- The furnace consists of a 0.63-mm-ID quartz tube filled with CuO. An outer element heats the tube to 850°C. The organic compounds are swept through the tube in a He stream.
- Passage from the furnace to the mass spectrometer is controlled by the pressure drop to the spectrometer vacuum system. The temperature-controlled cryogenic trap is set to -100°C to remove water from the combustion products.
- The mass spectrometer is a single-inlet, triple-collector instrument. δ -values are determined by comparison of the m/e 45/44 ratios of the sample and reference gases. Reference pulses are distributed around the sample peaks (e.g., see Fig. 2).

Fig. 2. Idealised GC-IRMS trace for standard mixture B. Flat-topped peaks indicate reference gas pulses, sharp peaks represent C_{19} – C_{24} *n*-alkanes.

mass spectrometric results (Craig, 1957).

The GC-IRMS technique was first developed by Sano et al. (1976) for the detection of

^{13}C -enriched metabolites from human patients. An improved technique was described by Matthews and Hayes (1978), who achieved precisions better than $\pm 0.5\%$ for both $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$ in CO_2 and N_2 , and were able to detect enrichments of the heavy isotope as low as 0.004% excess. The advent of commercially available GC-IRMS systems capable of determinations of $^{13}\text{C}/^{12}\text{C}$ at natural abundance levels (there is also a conceptually similar Finnigan® instrument) realises an opportunity to develop an entirely new field of research into the distribution of carbon isotopes in organic matter. However, the general availability of such technology also necessitates a thorough assessment of errors induced by the combination of the GC, interface and mass spectrometry.

ter, and the utilisation of a continuous flow system.

Here we report the initial results of investigations into some potential instrumental effects influencing the specific GC-IRMS system in use at SURRC. The tests involved analysis of two standard mixtures: A, containing decane, undecane, dodecane and methyl-decanoate; and B, composed of C_{19} to C_{24} *n*-alkanes. The isotopic compositions of the standard compounds were determined by the conventional sealed-tube combustion technique, to precisions better than $\pm 0.1\text{‰}$ (1σ). Mixture A was injected using the split injection method where the bulk of the sample is lost through a split vent, and only a small proportion (3% during this investigation) enters the chromatography column. Mixture B was injected in splitless mode, where the split vent is closed and a large proportion of the sample enters the column. Experiments have shown that there is no isotopic discrimination associated with split injection (SURRC, unpublished data, 1990). $30\text{ m} \times 0.22\text{ mm ID OV1}^\circ$ (non-polar) and DB5 $^\circ$ (medium polarity) columns were used during the course of the investigation. Furnace tube characteristics were also changed as explained on p.76.

2. Sample/reference imbalance

One obvious potential source of error arises from differences in the maximum major beam intensity (^{44}I) between the reference and sample gases. In conventional isotope ratio mass spectrometry $^{44}\text{I}_{\text{sample}} = ^{44}\text{I}_{\text{reference}}$ thus obviating pressure effects, etc. In complex samples, composed of compounds with differing relative concentrations, sample/reference beam balancing is not possible for all components. To assess the effects of sample/reference mismatch, the $^{44}\text{I}_{\text{sample}}/^{44}\text{I}_{\text{reference}}$ ratio (S/R), was varied by analysis of increasing amounts of mixture A at fixed reference gas pressures. The results show that for $S/R < 0.5$ (injection of $< 1500\text{ ng}$ of sample at 40:1 split ratio), the

error in accuracy ($\Delta^{13}\text{C} = \delta_{\text{measured}} - \delta_{\text{known}}$) reaches almost -3‰ (Fig. 3). For $S/R > 0.5$, $\delta^{13}\text{C}$ remains consistent, yielding accuracies of $\leq 0.55\text{‰}$ and precisions (1σ) $\leq 0.63\text{‰}$. Fig. 3 implies that in the analysis of complex mixtures, accurate determinations on small peaks may be difficult to achieve. The possible reasons for the trends observed in Fig. 3 are discussed below.

2.1. Pressure effects

Pressure effects are manifest as an interdependence of the ion-beam intensities ratio (45/44) with ^{44}I (Craig, 1957). The effect has been attributed to a variety of factors especially contribution of ^{44}I to the minor collector as a result of peak broadening. For example, Craig (1957), in assuming a functional dependence proportional to $(^{44}\text{I})^2$, proposed a Coulombic effect within the major ion beam. Mook and Grootes (1973) claimed that peak broadening was due to ion scattering only. Fallick and Baxter (1977) have demonstrated a linear correlation between the major beam tail contribution to the minor beam collector and the abundance of target molecules available for collision within the spectrometer. The reliance of the Isochrom $^\circ$ on a He stream necessitates tolerance of a plethora of target molecules in the analyser, thus enhancing peak broadening. If pressure effects can be caused by peak broadening and if $^{44}\text{I}_{\text{sample}} \ll ^{44}\text{I}_{\text{reference}}$, variation in contributions of mass-44 ions to the minor beam could result in the computation of low sample δ -values.

However, Fig. 4 indicates that for ^{44}I from $1.5 \cdot 10^{-10}$ to $1 \cdot 10^{-8}\text{ A}$ there is no significant interdependence between the reference gas 45/44 ratio and ^{44}I (there is a slight increase in 45/44, where $^{44}\text{I} > 1 \cdot 10^{-8}$). Further, Fig. 3 indicated that there is no corresponding increase towards positive $\Delta^{13}\text{C}$ -values when $S/R > 0.5$ as might be expected if a significant pressure effect was influencing the results. Our results support the statement of Fallick and Baxter (1977) that overlap of the major beam into the

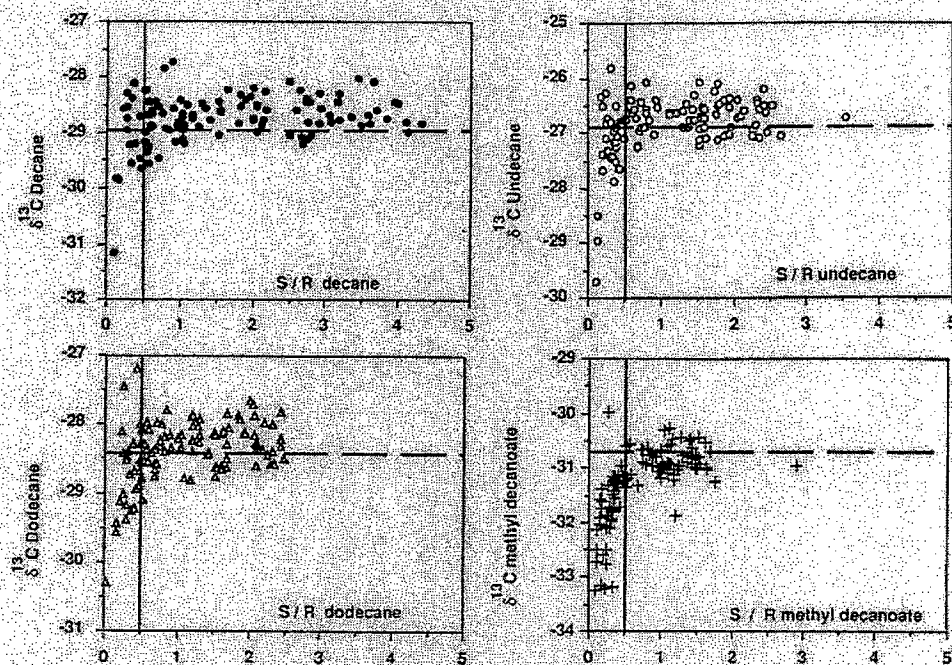

Fig. 3. $\delta^{13}\text{C}$ (‰ vs. PDB) of compounds in mixture A, plotted against S/R peak height ratio. Solid vertical line indicates $S/R=0.5$; dashed horizontal line indicates known isotopic composition (by conventional analysis). It is apparent from this figure that careful consideration must be given to accuracy, i.e. the relationship between δ_{isochrom} and δ_{known} for a given compound. A systematic offset in accuracy, whose origin is at present unknown, is noted for peaks 1–3.

Fig. 4. Reference gas 45/44 ratio plotted against major beam intensity. The total variation could account for errors $\leq \pm 0.5\%$.

minor collector could not be responsible for pressure effects under the conditions of their experiment, as a purely additive component to the minor beam results.

We conclude that sample/reference imbalance is not responsible for the diminution in $\delta^{13}\text{C}$ evident in Fig. 3. Therefore, the results must be attributed to an instrumental effect associated with small sample analysis, or to the presence of contamination in the spectrometer source. The latter may be related to efficiency of the cryogenic trap, which is responsible for removal of impurities from the sample gas stream.

3. Sample gas purification

Removal of water from the sample He flow is achieved by controlled cooling of the combustion products to -100°C . The cold trap consists of a coil of $\frac{1}{32}$ -in (~ 0.8 mm) stainless-steel capillary wound round the top of a copper pipe. The other end of the pipe is sub-

merged in liquid nitrogen. The capillary is heated to -100°C by means of a heated coil wound outside the capillary. The temperature is controlled by a thermocouple positioned between the steel capillary and the copper pipe. Even distribution of the heat from the element is achieved through a conductive layer of copper tape wound between the steel capillary and the heated coil.

We have found that incorrect positioning of the heating element and thermocouple in the water trap assembly can lead to inefficient trapping of water. Furthermore, defrosting of the water trap overnight releases the trapped water. Although most will be lost to the vacuum pumps, some coats the capillaries to the mass spectrometer, and thereafter can enter the spectrometer source. The presence of water in the source is marked by an increase in the reference gas 45/44 ratio. However, during the course of a day's operation a systematic decrease in 45/44 ratio is observed as the water clears from the capillary (Fig. 5). When water trapping is grossly inefficient, the reference gas 45/44 ratio increases markedly. The exact mechanism by which this increase is achieved is unclear at the moment. However, the practical effect evident from our analysis is that low $\delta^{13}\text{C}$ of sample peaks result (Fig. 6). Furthermore, there is a positive linear correlation between the isotopic composition of consecutive

Fig. 5. Systematic variation in reference gas 45/44 ratio with time as a result of gradual clearing of water from the sample line capillary.

Fig. 6. Graphical representation of the effects of water-trap defrost on $\delta^{13}\text{C}$ -values of C_{19} and C_{20} *n*-alkanes in mixture B.

compounds eluting from the GC column (Fig. 7). This relationship holds for all peaks in both standard mixtures, and may result in the final peak having the greatest inaccuracies (always negative) of all peaks analysed (Table 1). To minimise such effects we recommend strict adherence to the water-trap structure now adopted by the manufacturers, and daily baking of the trap to prevent release of water to the capillaries during overnight defrosting.

Although anomalously negative $\delta^{13}\text{C}$ -values in sample peaks result, it is difficult to envisage how inefficiency in water trap perform-

ance could lead to the large errors evident in Fig. 3. Therefore, we assume that the errors generated where $S/R < 0.5$ are due to sample size constraints.

4. Furnace performance and sample size constraints

$S/R < 0.5$ (Fig. 3) corresponds to sample sizes decreasing from 1500 to 50 ng. To investigate data variability with sample size, multiple analyses of mixture B were performed. Splitless injection was used in an attempt to ensure consistent sample sizes were analysed. During the experiment the furnace tube packing was varied to gain information on conditions for optimum performance.

A furnace tube (600 mm × 0.65 mm ID) was

filled with coarse (0.35–1 mm grade) wire from copper oxide granules. The coarse filling was chosen to provide a low surface area for combustion, combined with high gas permeability and velocity through the furnace tube. Thirteen determinations on 10-ng aliquots of each *n*-alkane in mixture B (Table I) yielded accuracies generally better than $\pm 1.5\%$ (worst case $\pm 2.2\%$) and precisions generally better than $\pm 0.6\%$ ($\pm 0.89\%$ worst case). The experiment was then repeated with injection of 70-ng samples (corresponding to $S/R > 0.5$ in Fig. 3). The results (Table I) show improved precision ($\leq \pm 0.62\%$) and accuracy ($\leq \pm 1.25\%$ for peaks 1–5 and $\pm 1.86\%$ for peak 6).

Plotting the total variance ($\sum d^2 C_{C_{19}-C_{24}}$) against the weighted bulk isotopic composi-

Fig. 8. a. Weighted mean isotopic composition of mixture B, calculated for repeated analysis of 10-ng (filled squares) and 70-ng (open circles) samples, plotted against total accuracy error for each run (solid line=10 ng, dashed line=70 ng; star indicates known isotopic composition). Furnace filling=0.35–1-mm-grade CuO.

b. Weighted mean bulk composition of mixture B plotted against total sample peak area for 10-ng (solid squares) and 70-ng (open circles) samples. (Regression line for 10-ng samples only; star indicates known composition.) Furnace filling=0.35–1-mm-grade CuO.

tion* (Fig. 8a) reveals that for both 10- and 70-ng sample sets the measured carbon isotopic composition is systematically depleted relative to the known isotopic composition calculated from determinations by conventional sealed-tube combustion. There is also an

*Bulk $\delta^{13}\text{C}_{\text{sample}} = m_n \delta^{13}\text{C}_{\text{alkane } n} + m_{n+1} \delta^{13}\text{C}_{\text{alkane } (n+1)} + \dots$ where m =proportion of total sample gas contributed by combustion of that compound; and n =number of carbon atoms in the lowest homologue in the series forming the standard mixture.

inverse linear correlation between the total variance and the weighted mean isotopic composition for both data sets. Furthermore, the range of total variance is reduced for the 70-ng compared to 10-ng samples. These results imply a link between sample size and accuracy. This is confirmed on cross-plotting the total sample peak area and the weighted mean bulk isotopic composition for each 10-ng analysis (Fig. 8b).

Despite attempts to inject consistently 10-ng quantities of sample, there is a two-fold variation in the amount of CO_2 analysed by the mass spectrometer (Fig. 8b). Additionally, injection of 70-ng samples is not reflected in a seven-fold increase in the amount of CO_2 analysed.

Variability in CO_2 abundance and $^{13}\text{C}/^{12}\text{C}$ on combustion of 10-ng samples (Fig. 8b) may be explained through incomplete mixing of CO_2 and He in the furnace tube. Gas is sampled at the open split, at a rate of $\sim 3 \text{ ml min}^{-1}$ (J. Jumeau, pers. commun., 1991), utilising the pressure drop, along the connecting capillary, to base pressure (10^{-9} Torr) in the analyser. Combustion of 70 ng of alkane must yield sufficient gas to saturate the He stream, effec-

Fig. 9. Weighted mean isotopic composition of mixture B plotted against total sample peak area for 10-ng (solid squares) and 70-ng (open circles) samples. Above 20 area units there is no systematic variation in the bulk isotopic composition. Furnace packing=0.35–0.5-mm-grade CuO.

tively limiting the amount of CO_2 which can be sampled as a pulse passes through the furnace tube. In contrast, where the He stream is not saturated and homogeneous, selective uptake of $^{12}\text{CO}_2$, via a kinetic isotope effect, may generate erroneously low $\delta^{13}\text{C}$ -values. The latter effect may be more pronounced at low CO_2 abundances leading to the relationship evident in Fig. 8b.

The above experiment was repeated using a 0.65-mm-ID furnace tube filled with fine (0.35–0.5 mm grade) copper oxide. The results reveal a marked reduction in accuracy error and improved precisions (Table 1). Furthermore, for total peak areas > 20 area units, there is no interdependence between $^{13}\text{C}/^{12}\text{C}$ and CO_2 abundance (Fig. 9). Curtailed gas flow velocity and permeability through the finer packing must ensure a relative increase in the CO_2 abundance in the He stream and improved homogenization of the gas mixture.

From Fig. 8b it is evident that where isotopic fractionation at the open split is overcome (e.g., during analysis of 70-ng samples), the results are still ~1‰ lower than the known isotopic composition. In hindsight, we must conclude that during the period of this investigation the water trap in use was not effective, and resulted in measurement of low $^{13}\text{C}/^{12}\text{C}$ ratios as a result of the instrumental effects eluded to on p. 74.

Data acquired using a properly constructed water trap known to be working well (Table 1) shows further improvement in accuracy ($\leq \pm 0.63\text{‰}$) for 70-ng samples. There is a slight deterioration in precision although for all compounds, this remains better than $\pm 0.4\text{‰}$. Five determinations on mixture A (of lower-molecular-weight compounds) gave excellent precisions and accuracies ($\sigma_n \leq \pm 0.17\text{‰}$; $\Delta \leq \pm 0.15\text{‰}$). Evidently, there are other sources of instrumental error which affect higher-molecular-weight compounds. These sources of error, which are likely to be a function of boiling point, etc., are currently the subject of further investigation.

5. Conclusions

Measurements of reference gas $^{13}\text{C}/^{12}\text{C}$ ratios over a considerable range of major ion beam intensities (10^{-10} – 10^{-8} A) indicate that despite the continuous He flow to the mass spectrometer, there is no significant pressure effect resulting from peak broadening. This indicates that inaccuracy is unlikely to be introduced as a result of sample/reference imbalance.

From repeated analysis of standard mixtures we can also conclude that:

(1) There is a lower limit to sample size below which accuracy error increased dramatically. Errors approaching –3‰ have been induced by injection of small samples.

(2) A kinetic isotope effect at the open split may be responsible for much of the inaccuracy and poor precision, leading to erroneously negative $\delta^{13}\text{C}$ -values on sample peaks. This effect may be accentuated by use of coarse copper oxide furnace fillings which prevent complete mixing of the CO_2 -He stream. Fine copper oxide (0.35–0.5 mm grade) may promote gas mixing and decrease the kinetic isotope effect at the open split, resulting in improved accuracies and precisions.

(3) Water released from the cryogenic trap either through overnight defrosting, or through cold-trap inefficiency can also lead to erroneously negative sample values. This effect can be overcome by nightly baking of the cold trap, and strict adherence to the water trap structure currently recommended by the manufacturer.

(4) Analyses obtained at the optimum conditions determined in this study: (a) furnace tube packing = 0.35–0.5 mm grade, with (b) a well-maintained water trap gave precisions generally better than $\pm 0.4\text{‰}$ and accuracies better than $\pm 0.65\text{‰}$ on high-molecular-weight standards. Low-molecular-weight compounds gave excellent data (both precision and accuracy better than $\pm 0.2\text{‰}$). Further work is evidently required to determine sources of error

specific to higher-molecular-weight compounds.

REVIEW

Referencing strategies and techniques in stable isotope ratio analysis

Roland A. Werner and Willi A. Brand*

Max-Planck-Institute for Biogeochemistry, P.O. Box 100164, 07701 Jena, Germany

Received 5 December 2000; Revised 6 December 2000; Accepted 23 December 2000

SPONSOR REFEREE: T. B. Coplen, US Geological Survey, 431 National Center, Reston, VA 20192, USA

Stable isotope ratios are reported in the literature in terms of a deviation from an international standard (δ -values). The referencing procedures, however, differ from instrument to instrument and are not consistent between measurement facilities. This paper reviews an attempt to unify the strategy for referencing isotopic measurements. In particular, emphasis is given to the importance of identical treatment of sample and reference material ('IT principle'), which should guide all isotope ratio determinations and evaluations. The implementation of the principle in our laboratory, the monitoring of our measurement quality, the status of the international scales and reference materials and necessary correction procedures are discussed. Copyright © 2001 John Wiley & Sons, Ltd.

Roughly 15 years ago a new and relatively economic chromatographic method to measure stable isotope ratios with high precision became commercially available. Carrier gas or on-line isotope ratio analysis systems now cover a wide range of applications and have led to a dramatic increase in the number of stable isotope ratio measurements worldwide. Although this has been a benefit to this field of science as a whole, it has also created a number of problems. We feel that the depth of knowledge that the few original experts possessed has been diluted considerably over the years with the consequence that the overall precision and reliability of isotope ratio values may have declined. In particular, the accuracy of reported δ -values relative to an international standard may have suffered from the vast increase in analyses made.

On the other hand, such a large increase in the number of analyses offers the opportunity to establish fully automated analysis sequences that include a proper referencing strategy. This opportunity should enable the reliability of isotope ratio value assignment to be improved. Although this has happened to a certain extent in many laboratories, referencing strategies have certainly not been unified throughout the community.

This review will be of considerable value both in

educating students and also newcomers to the exciting field of high precision stable isotope ratio measurements. In particular, we want to emphasize techniques for reliable standardization in carrier gas or on-line techniques where an accepted protocol for assigning δ -values^a on an internationally accepted scale has not yet been defined. We feel particularly suited for this task because we were given the opportunity to start a large isotope ratio measurement facility from scratch two years ago and thus had to develop all the techniques and protocols for such an endeavor recently.

Stable isotope ratios and their international scales

The stable isotope ratios measured most widely include $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$ and $^2\text{H}/^1\text{H}$ (or simply D/H). Other less frequently measured ratios are inter alia $^{17}\text{O}/^{16}\text{O}$, $^{34}\text{S}/^{32}\text{S}$, $^{33}\text{S}/^{32}\text{S}$. The common feature of these ratios is that they can be determined using a few light gases (CO_2 , CO , N_2 , O_2 , H_2 , and SO_2). Hence they share a common technology termed (Gas) Isotope Ratio Mass Spectrometry.

The principle of the classical method is very easy to understand: Two gases are stored in containers connected via capillaries to a switching unit, the 'changeover valve'¹ (Fig. 1). The latter serves to direct one of the gases to the ion source of an isotope ratio mass spectrometer (IRMS)^{2,3,4,5,6} while the other gas flows to a waste vacuum line, and vice versa. The ion currents are measured separately from both gases and compared a number of times. The measured relative difference in ion current ratios is then calculated relative to an internationally agreed isotope ratio scale.

Table 1 is a compilation of the international stable isotope ratio scales in use together with the presently accepted absolute ratios and their errors. When comparing samples

^a The variation of stable isotope ratios in nature is small. The small differences are conveniently expressed as delta values (δ) in per mill [‰] deviation from a reference^{2,3,8} according to

$$\delta[\text{‰}] = (R_{\text{sa}}/R_{\text{ref}} - 1) \cdot 1000 \quad (1)$$

R_{sa} and R_{ref} are the sample and reference isotope ratios, respectively.

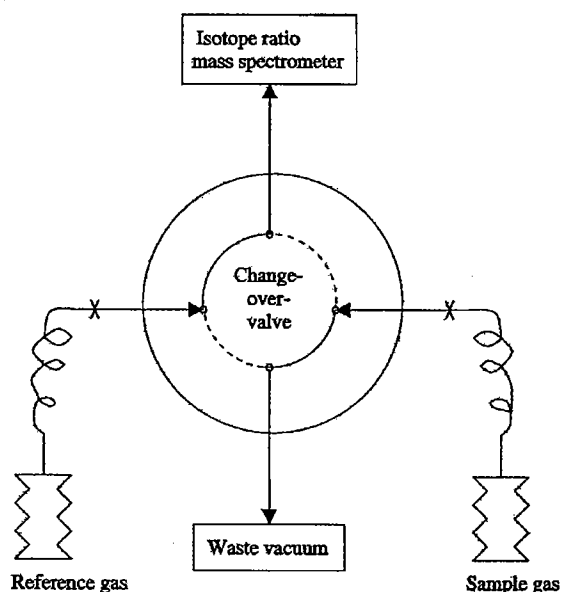

Figure 1. Schematic representation of a dual inlet system featuring the 'Changeover Valve' as the classical referencing technique in Stable Isotope Ratio Mass Spectrometry. While the gas in one volume is flowing to the mass spectrometer, the gas in other goes to a waste line and vice versa.

with one of the standard materials, however, the errors are generally considerably smaller owing to the fact that a relative measurement has far fewer sources of error than an absolute determination.

Carbon

The international scale for $^{13}\text{C}/^{12}\text{C}$ started as a carbonate laboratory standard for oxygen and carbon isotope ratios in the group of Harold Urey at the University of Chicago in the early 1950s.^{7,8} Being representative for carbon in the lithosphere that precipitated from the world oceans, PDB was later proposed as the international reference material for the carbon and oxygen δ -scale by Harmon Craig.⁹ The Cretac-

eous belemnite material was picked from the Pee Dee formation in South Carolina, hence 'PDB' for Pee Dee Belemnite. The original material no longer exists. It has been replaced by assigning exact δ -values (both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}^b$) to another carbonate (NBS-19) relative to PDB.^{10,11} This new scale is termed 'VPDB' (Vienna PDB) in recognition of the role that the International Atomic Energy Agency (IAEA), located in Vienna, has played in redefining the PDB scale. The IAEA played a similar role for the other δ -scales that have a 'V' preceding the original scale name.

Unfortunately, isotope ratios of CO_2 must be determined using the molecular ion masses 44, 45 and 46. The ^{13}C information comes in disguise. It is available from the 45/44 ion current only after subtracting the $\sim 7\%$ contribution from $^{12}\text{C}^{17}\text{O}^{16}\text{O}^+$ (see 'Correction of isobaric interferences'). This complicates the exact comparability of $\delta^{13}\text{C}$ values between different laboratories.

Oxygen

High precision isotope ratio measurements of oxygen were first made on CaCO_3 , O_2 and H_2O . Again it was Urey's group that developed these applications for paleoclimate reconstruction.^{2,19,20,21} The two accepted international scales (VSMOW and VPDB) have developed over time. A variety of carbonate (including PDB) and water standards were used until 1961, when Harmon Craig proposed SMOW (Standard Mean Ocean Water). SMOW isotopically represents the hydrosphere with the world oceans as the largest reservoir of oxygen (and hydrogen). Interestingly, the standard that Craig proposed was not available as a reference material. It had a δ -value that was believed to represent average ocean water based on experience accumulated over time. It was precisely defined relative to the (now exhausted) water standard NBS-1 that was almost 8‰ off the new $\delta^{18}\text{O}$ -scale and 47.6‰ off the simultaneously defined δD -scale. Both Craig and the IAEA engaged in developing a reference material with an isotopic composition of SMOW, which led to the current VSMOW scale. This material presently is still available in limited amounts from the IAEA in Vienna. A new batch of reference water matching the VSMOW scale as closely as possible in all isotope ratios is currently being prepared.

$^{18}\text{O}/^{16}\text{O}$ ratios are measured using CO_2 after appropriate conversion from the original material. Due to the fact that the

^b $\delta^{18}\text{O}_{\text{NBS-19}} \equiv -2.2\text{‰}$ vs. VPDB; $\delta^{13}\text{C}_{\text{NBS-19}} \equiv +1.95\text{‰}$ vs. VPDB

Table 1. International isotope ratio scales¹²

| Isotope ratio | International scale | Accepted ratio [$\times 10^6$] | Error of ratio | Error of ratio [%] | Ref. |

| $^{34}\text{S}/^{32}\text{S}$ | VCDT | 44150.9 | ± 11.7 | ± 0.27 | Ding <i>et al.</i> ¹⁸ |

Isotope ratios are reported as δ -values in per mill (‰) deviations from the origin of the respective international scale. Please note that for oxygen two internationally accepted scales coexist.

^c Chang and Li report a $^{13}\text{C}/^{12}\text{C}$ value of 0.011202 for NBS-19. The $\delta^{13}\text{C}$ -value of NBS-19 is +1.95‰, defining the VPDB scale. The previously established $^{13}\text{C}/^{12}\text{C}$ PDB ratio value⁹ of 0.0112372 is 5‰ higher.

behavior of terrestrial ^{17}O and ^{18}O are closely linked via mass fractionation laws, $^{17}\text{O}/^{16}\text{O}$ ratios (measured using O_2 gas) are analyzed only occasionally.

When carbonates or CO_2 in air are measured, oxygen isotope ratio values are preferentially reported on the VPDB or VPDB_{gas} scale and this can lead to confusion when the scales are not stated explicitly. The reason for the coexistence of two oxygen scales is that measurements of δ -values against a chemically identical or similar reference can in principle be made with enhanced precision. VPDB has a $\delta^{18}\text{O}$ value of +30.92‰²² on the VSMOW scale. The CO_2 gas 'developed' from hypothetical VPDB (= VPDB_{gas}) at 25°C using pure, water-free H_3PO_4 is 10.25‰ heavier;^{23,d} it has a $\delta^{18}\text{O}$ value of +41.5‰ on the VSMOW scale. It should be noted that δ -values can not be added or subtracted in a simple way when referring to different standards.^e

Hydrogen

The isotopes of hydrogen have the largest relative mass difference. Since most isotope fractionations in nature roughly scale with relative mass difference, the largest variations in terrestrial isotope ratios are found for hydrogen. Although the large mass difference makes the isotope signatures easier to detect, the low abundance of deuterium (only about 150 ppm in ocean water) can create problems during high-precision analysis. Consequently, two international reference materials are in frequent use to cover the natural range of isotope ratios for D/H. The basis of the international scale is the same as oxygen, VSMOW. The other reference material is a water sample named SLAP (Standard Light Antarctic Precipitation) that is, relative to VSMOW, more than 42% depleted in deuterium (−428‰). The difference between VSMOW and SLAP is used to correct for the nonlinear behavior of instrumentation and (or) sample preparation during analysis.

Nitrogen

Unlike the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in atmospheric CO_2 , the $\delta^{15}\text{N}$ value of atmospheric N_2 does not change within measurement precision over time or space.^{24,25} This is due to the fact that the atmospheric pool of nitrogen is by far the largest of all nitrogen-bearing pools on earth and thus cannot be altered significantly by known processes. It participates in all natural processes as source and sink so that the net change over time is close to zero. Consequently, AIR- N_2 has been adopted as the international reference material for all nitrogen isotope ratio analyses. This does not imply that the isotope ratios are easy to measure. From air, N_2 must be isolated without isotopic fractionation for use as a primary reference. For convenience (and thus enable better data comparability) the IAEA has made secondary standards (mostly ammonium and nitrate salts) available for direct use in sample preparation lines involving combustion.

^d More recently, a value of 10.44‰ has been reported by Kim and O'Neil.⁵²

^e The δ -value for a sample (sa) measured against a working standard (ws) on an international scale (is) is given by

$$\delta_{\text{sa/is}} = \delta_{\text{sa/ws}} + \delta_{\text{ws/is}} + \delta_{\text{sa/ws}} \times \delta_{\text{ws/is}}/1000 \quad (2)$$

Sulfur

Sulfur is most commonly measured as SO_2 gas on the molecular ion masses 64 and 66. Unfortunately, the isotopes of oxygen directly interfere with the sulfur isotopes (isobaric interferences) at these mass positions and thus cannot be measured independently (the ion current at m/z 66 comprises $^{34}\text{S}^{16}\text{O}_2^+$ and $^{32}\text{S}^{16}\text{O}^{18}\text{O}^+$). Using SF_6 as the measurement gas avoids this problem, but preparation of SF_6 requires fluorine gas as a reagent and preparing clean SF_6 is difficult. Hence, SF_6 has found only limited use. The international δ -scale is defined by VCDT (Vienna Cañon Diablo Troilite)²⁶ The original CDT,²⁸ adopted as the primary standard in 1960, was prepared from the FeS phase of a large iron meteorite found at Meteor Crater, Arizona. Improved measurement precision has revealed that CDT is not sufficiently homogeneous²⁷ to be continued as the primary reference material and, as a consequence, the CDT scale has been replaced with VCDT. VCDT is defined by assigning a $\delta^{34}\text{S}$ -value of −0.3‰ (exactly) to IAEA-S-1 (formerly NZ-1, Ag_2S).²⁶ It is worth noting that the absolute $^{34}\text{S}/^{32}\text{S}$ ratio in VCDT given in Table 1 differs from the previously established value (45004.5)²⁸ for CDT by about −20‰. This affects the correction for ^{18}O contribution (see 'Correction of isobaric interferences').

Referencing techniques in isotope ratio mass spectrometry and the principle of identical treatment

Dual inlet system and changeover valve. The breakthrough in classical isotope ratio mass spectrometry was the dual inlet mass spectrometer, introduced by Urey in 1948² and described by McKinney *et al.* in 1950.³ Despite significant improvements in electronics, vacuum system design and full computerization, the basic principles embodied in this mass spectrometer still form the basis of modern stable isotope ratio mass spectrometers for high-precision analysis of clean analyte gas.

A key feature of the McKinney instrument is the 'changeover valve'¹ (Fig. 1), which allows continuous flows of reference and sample gas to be alternated between the mass spectrometer and a waste line vacuum pump. The 'changeover valve' is the classical referencing technique. Together with the dual variable volume (or mercury piston) reservoir system for introduction of sample and reference gases, it allows a direct comparison of ion currents and ion current ratios. Instrumental effects like temporal fluctuation of sensitivity or temperature drifts cancel almost completely.

In order to avoid isotopic composition changes of the gas in either reservoir over time due to molecular effusion into vacuum, the connection between the gas reservoirs and the 'changeover valve' is made with thin capillaries (0.1–0.2 mm i.d.) of about 100 cm length that are crimped near the end.²⁹ The hole right at the capillary crimp also constitutes a molecular leak. However, provided the pressure in the capillary is sufficiently high (typically >50 mbar for hydrogen and >15 mbar for other gases), the flow through the capillaries is viscous, not molecular, and thus prevents the isotopically enriched gas at the crimp from diffusing back into the reservoirs.⁴ This viscous flow condition establishes a

Table 2. Measurement of two CO₂ gas samples by different laboratories

| $\delta^{13}\text{C}$ [‰ VPDB] | | | | | | | |

| GS-20 | -8.622 | -8.624 | -8.617 | -8.635 | -8.575 | -8.615 | 0.0231 |
| $\delta^{18}\text{O}$ [‰ VPDB-CO ₂] | | | | | | | |
| Sample | CIO | INSTAAR | CSIRO | Heidelberg | Scripps | mean | std. dev. |
| GS-19 | -0.193 | -0.790 | -0.617 | -0.426 | -0.126 | -0.430 | 0.280 |
| GS-20 | -0.991 | -1.580 | -1.380 | -1.191 | -0.915 | -1.211 | 0.274 |

lower limit to the minimum amount of gas that can be determined with high precision. Small amounts of gas may be frozen into a small volume ('microvolume') in front of the capillary. Making this reservoir as small as is physically possible (~250 μL) and operating at 15 mbar results in a minimum sample size of about 4 μL^{f} gas.

Using modern dual inlet mass spectrometers it is possible to obtain a precision of 0.01‰ for $\delta^{13}\text{C}$ (and similar values for other isotope ratios) by comparing the ion current ratios of the gases in both reservoirs a number of times for several seconds. The mean is calculated and such measurements are compared a number of times during the course of a day. However, precision is not the same as accuracy. On the next day the results may again be very precise. The mean, however, may differ from the mean from the previous day, or from the previous week, month, or year.

The situation is illustrated by results from a recent intercomparison of CO₂ gas initiated by the Groningen Centre for Isotope Research (CIO).³⁰ The ring test involved two gases (GS-19 and GS-20) sent to five prominent laboratories for isotopic determination. The results from the ring test are given in Table 2.

The precision of the $\delta^{13}\text{C}$ -values is approx. 0.025‰ and appears acceptable, whereas the $\delta^{18}\text{O}$ data show an unacceptably large scatter. This finding is attributed to different referencing methods or materials in the laboratories. If GS-19 is used as the reference (δ -value set to 0.0‰) and GS-20 measured against it, the precision of the reported differences improves to 0.009‰ for $\delta^{13}\text{C}$ and 0.016‰ for $\delta^{18}\text{O}$. Through direct referencing, the $\delta^{13}\text{C}$ results are improved by a factor of 3 and the $\delta^{18}\text{O}$ situation improves almost 20-fold.

How can the precision that these mass spectrometers are obviously able to deliver be conserved and converted into an accuracy figure over long time periods? How can different mass spectrometers deliver results that can be compared reliably at a precision level of 0.01‰?

These questions require some discussion before a more

general conclusion can be reached. Several points need to be considered:

- The capillaries to the 'changeover valve' are carefully heated and the inlet system is conditioned until the ratios for the same gas, introduced to both reservoirs, is close to zero ('zero enrichment test').⁸ However, in the real world, the two gases are different and may even differ in their trace gas impurities. Traces of water or other protonation agents can give rise to an isobaric interference of CO₂H⁺ (m/z 45) resulting from ion/molecule reactions in the ion source. Similar protonation reactions are possible for other gases resulting in H₃⁺ or N₂H⁺.
- The isotopic composition of a sample and reference gas should not be very different; however, in reality, they always will be and, as a consequence, balancing the major ion beam means that the minor beams will have different readings. If the response of the measurement channels is not perfectly linear (and it never will be), this is a source of error that can vary with time.
- The measurement precision and results for $\delta^{18}\text{O}$ from CO₂ gases depend critically on the nature and the cleanliness of the internal surfaces of the reservoir and the transfer capillaries. Not only can CO₂ exchange oxygen with surface water, it may even exchange with other forms of loosely bound oxygen on the surface and hence cause uncontrolled isotopic fractionation. This may be different for the two capillaries and may change over longer time periods.
- Different mass spectrometers (even from the same manufacturer) can have several sources of error in determining a given isotopic difference. This has been shown for hydrogen where the isotope ratio differences are often large. It is also important for other gases like CO₂ when the measured δ -values differ by 10‰ or more and the required accuracy is high.

It is common practice in laboratories that strive for the highest long-term precision and accuracy to have sample and reference gas measured from the same (sample) reservoir of the dual inlet system. The gas in the reference volume serves as a temporary mediator between the different runs. Proceeding in this manner, sample and reference gas are handled in a highly comparable, almost equal, fashion and, as a result, some (but not all) of the errors discussed above tend to cancel out.

^f 1 μL ('bar microliter') is an amount of 1 μL gas at STP.

⁸ Please note that crimping of the capillaries will not necessarily result in the same signal height for the same gas pressure on both sides. In fact, when referencing through the sample line ('IT principle'), it is more important to have a long lifetime for the standard gas and thus make the crimp for the capillary tighter on this side.

Figure 2. Referencing technique in isotope ratio monitoring applications. Helium enters a small glass tube through a fused-silica capillary. Another fused-silica 'sniffing' capillary (usually 1000 mm long and 0.1 mm i.d.) connects to the ion source of the mass spectrometer. Reference gas pulses are generated by moving a third capillary between two positions, one upstream and the other downstream from the sniffing point.

The IT principle

We will refer to 'Identical Treatment' of sample and reference material as the 'IT principle' for relative measurements. The IT principle, which does not apply exclusively to the dual inlet technique, serves excellently for maintaining long-term laboratory performance records for other isotope ratio measurement techniques as well (see 'Performance charts').

It is rare that the measurement gas is identical to the original sample. Typically, a carbonate, a water sample, an organic compound, a piece of bone, soil, hair or a gas mixture etc., is selected from which the measurement gas has to be produced or extracted. During this transformation it is critical to avoid isotopic alteration. In carbonate analysis or water equilibration the IT principle has been common practice for a long time. Carbonates are effectively standardized by running carbonate reference material alongside the samples on a daily routine basis. Water samples are equilibrated together with reference water standards in the same temperature-controlled bath. Because the isotopic fractionation occurring in the CO_2 liberation or the isotope transfer reaction to the gas phase is strongly temperature dependent, the reference material is subjected to the same reaction conditions. The isotopic fractionation cancels as long as the chemical nature of sample and reference is closely comparable. The same argument applies to water reduction methods for hydrogen isotope ratio analysis. Here, irrespective of the specifics of the reduction process, the

potential for isotopic fractionation is encountered in almost every detail of the reaction including the type of vessel, the temperature, the amount of reduction material, and the timing sequence of the reduction reaction. Hence, running reference water samples concurrently with unknown samples in every batch is required in order to obtain reliable results.

Isotope ratio monitoring techniques

Isotope ratio monitoring ('irm') encompasses all techniques for high-precision determination of stable isotope ratios that employ a helium carrier gas for transferring the analyte gas as a transient into the isotope ratio mass spectrometer.³¹ The term 'irm-GC/MS' was introduced by D.E. Matthews and J.H. Hayes in their pioneering paper in 1978.³² Popular acronyms in common use for specific irm couplings are GC/C/IRMS (GC/combustion/IRMS) and EA/IRMS (elemental analyzer/IRMS). The techniques were originally developed to measure $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$. More recently, D/H, $^{34}\text{S}/^{32}\text{S}$ and $^{18}\text{O}/^{16}\text{O}$ ratio determination has become available, accompanied by a host of new acronyms.

In irm systems the sample gas leaves the appropriate sample preparation and separation device as a peak entrained in helium. The chromatographic separation not only ensures that the analyte gas is pure or coming from a single precursor, it also separates the stable isotopes (i.e. isotopomeric molecules) of the analyte to a certain extent. In irm-GC/MS applications the separation often exceeds 100 ms between e.g. the ^{13}C moiety of the analyte, which elutes first, and its ^{12}C counterpart.^{31,33}

Referencing can be carried out in a number of ways. The most common method is to inject pulses of reference gas directly into or in parallel to the GC effluent stream.³⁴ The time window or windows for the reference gas pulses must be carefully selected in order to avoid interference with any analyte material entering the mass spectrometer concurrently. Other methods include the admixture of reference compounds to a GC mixture (internal standards) or, less favorably, the direct comparison of ratios from chromatogram to chromatogram.

Figure 2 shows schematically an example of a reference gas injection mechanism. Inside a closed, thin (<1 mm) glass tube, the effluent stream from the interface is fed in continuously with a fused-silica capillary. Downstream a second fused-silica capillary acts as the transfer line to the mass spectrometer. Usually, this capillary has an internal diameter of 0.1 mm and a length of 1000 mm. Together with the pressure drop from atmosphere to about 10^{-5} mbar, this capillary allows for a flow of about 400 μL per minute. The flow through long, thin capillaries under viscous flow conditions follows the law of Hagen-Poiseuille. For a given pressure difference the flow is linked to the 4th power of the radius and linearly to the length of the capillary. Hence, when doubling the radius, the flow will increase by a factor of 16 while keeping the other parameters constant. The third capillary (see Fig. 2) serves to inject pulses of reference gas. Using a piston mechanism it can be switched between two positions: one upstream and one downstream from the sniffing point of the transfer capillary. Only the upstream position will deliver reference gas to the sniffing point.

Figure 3. Graphical output of a irm-GC/MS system, in this case from a Gasbench II run (see $\delta^{18}\text{O}$ determination). Three GC traces are monitored simultaneously with different sensitivity factors. The upper trace is an overview over the whole run. The middle window ('45/44 Ratio Trace') represents the instantaneous 45/44 ion current ratio. The first, flat-topped peak represents a post column injection of reference gas. For the sample peaks, please note the isotope swing going positive first which is indicative of the partial separation of the isotopomers on the GC column. Reference pulses do not show this behavior. At the flanks they exhibit a reaction to the fast changing intensity due to differences in the amplifier time constants.

Downstream the helium carrier will sweep away any effluent from capillary three. Figure 3 shows an example of a simple GC run (in $\delta^{13}\text{C}$ measurement mode). The first, flat-topped peak is a reference gas injection lasting for about 30 s. The other peaks are from sample gas analyses. Their shape is typical for this type of gas chromatography. Please note the variation of the instantaneous (45/44)-ratio along each GC peak going positive first due to the ^{13}C moiety eluting earlier than the pure ^{12}C compound.

The principle of moving capillaries in the open split region has been utilized in a number of ways. Multiple reference gases can be introduced, the GC effluent gas can be diluted with helium further to cover a wider dynamic range³⁵ or the transfer capillary may be switched into a clean helium cushion for 'heartcutting' (i.e. selecting or selectively discarding) GC peaks.

Other means of injecting reference gas pulses include rotary valves equipped with an injection loop or carefully designed multiple valve systems. The drawback common to all of these systems is that during switching a short interruption of the continuous flow of carrier gas occurs which leads to problems in the background definition of the reference gas peaks and, hence, to reduced precision.

It is important to note that referencing solely relative to reference gas pulses is an immediate violation of the IT principle introduced above. Sample peaks are generated from original material going through a combustion/separation or separation/combustion step whereas the (working)

reference is pure gas. The principle governing long-term precision and, more importantly, accuracy requires that sample and reference be identical in nature and follow the same sample isolation and conversion pathway. Hence, a *n*-heptadecane sample should be referenced with a *n*-heptadecane reference.

Often gas chromatograms are very complex. The conversion efficiency of *n*-heptadecane should be very close to *n*-hexadecane or *n*-octadecane. Even an *n*-C25 alkane should be a valid reference point provided the stability of the mass spectrometer is high and the conversion unit reliably works close to 100% yield. Hence, even whole chromatograms can serve as references in pursuit of the IT principle. In this case, reference gas pulses again take the role of a mere mediator between runs, very much as the standard gas in dual inlet analyses. In principle, the number of reference runs is determined by the precision required for the experiment in question.

The workhorse in most modern isotope ratio laboratories is the combination of an elemental analyzer with isotope ratio mass spectrometry (EA-IRMS or irm-EAMS, sometimes termed BSIA⁴ for bulk sample isotope analysis). As with irm-GC/MS, the immediate or working referencing is commonly made through co-injected reference gas pulses into the effluent stream. Earlier commercial versions of this instrumentation relied solely on comparing from sample to sample, without reference gas peaks. However, precision of a single measurement is improved when comparing

standard and reference more closely in time. Data security is an issue when a single result relies on the measurement of the whole sequence.

In order to work under the rule of the IT principle individual sample results versus a gaseous working standard can be compared with results from reference material that has passed the full sample line in the same sequence of measurements.

Day-to-day working environment for high-precision isotope ratio analyses and generation of performance charts

In our laboratory we have implemented a number of routine measurement schemes for the following types of analyses:

- $\delta^{13}\text{C}$ from bulk solid (and liquid) material (irm-EAMS system)
- $\delta^{15}\text{N}$ from bulk solid (and liquid) material (irm-EAMS system)
- δD from water samples (Cr-reduction/dual inlet)
- $\delta^{18}\text{O}$ from water samples ($\text{CO}_2/\text{H}_2\text{O}$ equilibration followed by irm analysis)
- $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ from CO_2 in air samples (cryogenic separation/dual inlet, in development)
- O_2/N_2 ratios in air samples (changeover system with open split, in development)

The first step in setting up routine protocols is the establishment of effective laboratory standards that can be used and monitored on a daily basis. General rules for laboratory standards are difficult to fix, they largely depend on the type of analysis.

The second step is the development of consistent analysis sequences, i.e. the decision how on a daily basis samples, reference material, and blanks (if applicable) are positioned in a sample carousel or autosampler. In this respect, economic aspects, such as the number of samples per day and week, scheduling of routine maintenance, number of samples per reactor, etc., are of importance and must be considered with great care and separately for every type of analysis. In our laboratory we have tried to adjust the measurement cycles to the diurnal and weekly cycle of the human operators, to optimize throughput without sacrificing precision.

Selection of laboratory reference materials

After having obtained the relevant primary reference material from the IAEA or other agency, secondary or laboratory standards must be prepared for every day use. The IAEA recommends not using the original material on a

daily basis. Primary reference materials in general are in short supply and their commercial availability is restricted.

For $\delta^{13}\text{C}$ analysis using a combustion technique, NBS-22 (-29.78‰ ^h vs. VPDB) is a valid reference material for almost any purpose. The secondary laboratory standard should be chosen according to the following criteria:

- easy to handle during weighing or other preparatory steps.
- preferably a pure single chemical compound.
- isotopically homogenous down to the smallest amount used during analysis.
- stable and constant in isotopic content over a long time period. For liquids, in particular water, large quantities are advantageous in order to minimize evaporation losses. The isotopic composition should be stable versus frequent use.ⁱ
- easy to replace if exhausted.
- chemically identical or close to the samples to be measured. This point must be evaluated in terms of the corresponding analysis. It is probably easy to use some oily material like NBS-22 for referencing almost any bulk combustion ($\delta^{13}\text{C}$). However, using carbonates for referencing water samples is more difficult if not impossible in pyrolysis systems ($\delta^{18}\text{O}$).³⁶
- the isotopic composition should be in the range of the samples to be measured. Isotopic differences can be measured most precisely when small. Because most natural organic material is produced primarily through C_3 -photosynthesis, $\delta^{13}\text{C}$ values around -25‰ vs. VPDB are recommended for the laboratory standard.
- non-hygroscopic. This is of particular importance for oxygen and hydrogen isotope ratio analysis using high-temperature carbon reduction ('pyrolysis') systems.

irm-EAMS

We analyze any bulk material that can be combusted quantitatively to CO_2 , N_2 and H_2O (+ other oxides if applicable) using the combination of an elemental analyzer (NA 1110, CE Instruments, Milan, Italy) with an isotope ratio mass spectrometer (DELTA⁺XL, Finnigan MAT, Bremen, Germany). The coupling interface is a ConFlo II[®], modified in-house to a ConFlo III,³⁵ which includes two open splits, one for the coupling, the other one for reference gas introduction. The coupling split can be varied over a wide range from zero to 64-fold dilution of the effluent stream without causing detectable isotopic fractionation. Two reference gases (mostly CO_2 and N_2 , alternatively H_2 and CO) can be actuated under computer control. H_2 and CO reference gases are used when the system operates in high-temperature 'pyrolysis' mode with a Finnigan MAT TC/EA for D/H or $^{18}\text{O}/^{16}\text{O}$ isotope ratio analysis. The operation of the system generally follows a well-defined protocol. Samples, reference material aliquots, and blanks are weighed and filled into the 32-position autosampler carousel according to a loading list (Fig. 4). Please note that each list represents samples for three carousels (we use 96-position sample trays for storing samples in a desiccator before measurement). It serves as input for the sequence information in the mass spectrometer control software.

The prefilled positions in the loading list are mandatory. They are used in a post-run off-line evaluation on a

^h The previously recommended value of -29.74‰ was adjusted to -29.78‰ by the 8th Advisory Group Meeting on Future Trends in Stable Isotope Reference Materials and Laboratory Quality Assurance, IAEA, Vienna, Sept. 18–22, 2000.

ⁱ Carbonates can exchange oxygen isotopes with air- CO_2 . This effect depends on grain size, humidity, nature of the carbonate, and frequency of opening when the material is kept under inert gas. Water reference material can alter its isotopic composition through evaporation and transpiration through container walls. Hence, the frequency of opening the reference water container can affect the isotopic stability. GC injection mixtures may change their isotopic composition and concentration via evaporation when low boiling point material is used as a reference.

Figure 5. Spreadsheet calculation of data from the irm-EAMS system showing the evaluation of the raw data to the final δ -values on an international scale. See text for further explanations.

Figure 6. Performance Chart. $\delta^{13}\text{C}$ -values of a quality control standard as a function of measurement time. The scale is based on reference material that went through the same preparation channel as the QA standard. Each sequence of 32 samples measured holds one QA standard that is represented by a single point.

standardized spreadsheet (Fig. 5) for assigning the final δ -values on the respective international scale.

The spreadsheet evaluation³⁷ starts with the original values directly transferred from the host computer ('ISO-DAT' from Finnigan MAT). Columns 1 to 5 (Fig. 5) hold information about the sample including the sample name and weight, the integrated peak area and the measured $\delta^{13}\text{C}$ -value based on the injected reference gas. The average peak area (Vsec) and δ -value (‰) of the blank measurement[†] are used to correct the data for blank contribution applying a simple mass balance correction.

$$\delta^{13}\text{C}_{\text{tot}} \times \text{area}_{\text{tot}} = \delta^{13}\text{C}_{\text{sa}} \times \text{area}_{\text{sa}} + \delta^{13}\text{C}_{\text{blk}} \times \text{area}_{\text{blk}} \quad (3)$$

The suffixes in Eqn. (3) refer to the total (tot), sample (sa) and blank (blk) properties, respectively.

Usually the correction is very small. The data in column 8 (Fig. 5) represent the blank-corrected preliminary $\delta^{13}\text{C}$ -values (‰) when the reference gas is used for standardization. The following columns denote the laboratory standards selected for further correction and final positioning of the data onto the VPDB scale. Ali-j1 (Acetanilide-Jena1) has been determined directly versus NBS-22 oil and USGS24 graphite a number of times and has been assigned a $\delta^{13}\text{C}$ -value of -33.94‰ on the VPDB scale. The measured average $\delta^{13}\text{C}$ -value of the selected Ali-j1 samples in Fig. 5 is -34.01‰ . Thus, there is an offset of 0.07‰ to the accepted δ -value that

[†] We found that the carbon blank in our laboratory mostly has a $\delta^{13}\text{C}$ -value around -25‰ vs. VPDB. The major contributions are carbon in the tin containers and memory in the combustion reactor. Often the blank area is so small that the $\delta^{13}\text{C}$ measurement is erroneous (outside the natural abundance range). In such cases we replace the wrong $\delta^{13}\text{C}$ -value of the blank by our average value, -25‰ .

is used to correct all data (Eqn. (2)). The data in column 13 are the final $\delta^{13}\text{C}$ -values on the VPDB scale. The last two columns are average and precision of the selected Ali-j1 data.

In principle, this procedure represents a one-point calibration of the $\delta^{13}\text{C}$ -values; our scale expansion factor is 1.000. For measuring larger differences in isotopic composition it will be necessary to include a scaling factor in the calculations (see Fig. 10 and the discussion in 'Further corrections').

Not shown in Fig. 5 are further routine calculations of the carbon elemental contents based on the measured peak area and the known carbon content of the reference material (Ali-j1, 71.09% C). The $\delta^{15}\text{N}$ analyses are made in a completely analogous fashion.

Generation of performance charts

We use one dedicated sample position for determining a QA standard (quality assurance), in this case Caf-j1 (a caffeine sample from a 'Traube synthesis' in larger supply), in every sample carousel we run. We have chosen this material because it is off the usual $\delta^{13}\text{C}$ values for C_3 -plants by about -20‰ . With this QA standard, which does not enter the reference calculation, the long-term performance of the irm-EAMS line has been monitored (Fig. 6 for $\delta^{13}\text{C}$ and Fig. 7 for $\delta^{15}\text{N}$).

Figures 6 and 7 are representative for all measurements made on our irm-EAMS systems (in total from three different mass spectrometers and two different interfaces) since we started routine analyses. We measured both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ from the same sample until April 1999. From the performance charts we noticed that the accuracy, especially for $\delta^{15}\text{N}$, was not satisfactory and needed improvement. Careful analysis of the data indicated that the problems were

Figure 7. Performance Chart: Same as Fig. 6 for $\delta^{15}\text{N}$ -values

caused by tailing of the CO_2 peak into the nitrogen chromatogram of the subsequent sample. Most materials analyzed had an elemental content of $\leq 2\%$ nitrogen and $\geq 40\%$ carbon. For analysis the CO_2 had to enter the GC column (Porapak Q) and, due to the relatively large amount, was still present and declining steadily during the subsequent nitrogen analysis. CO_2^{++} ions undergo unimolecular decay in the ion source resulting in a $10\% \text{CO}^+$ contribution at m/z 28 and 29 that interferes with N_2^{++} and has a very different isotopic signature. The background assignments of all peaks in the nitrogen chromatogram were affected and hence precision and accuracy suffered. As a consequence, we decided to stop simultaneous isotope ratio measurement

using irm-EAMS altogether. For $\delta^{15}\text{N}$ determination we now trap CO_2 in a chemical (Ascarite) trap installed between the water trap and the GC column of the elemental analyzer.

The performance or quality chart is also the perfect tool to monitor the status of the laboratory reference materials. Any contamination in either the laboratory standard or the QA standard will show up as a step. Slow long-term alteration (e.g. evaporative loss in water standards) will show as a drift. We recommend using such charts as a general tool for maintaining and proving analytical performance in every isotope laboratory for every type of analysis.

In order to demonstrate the effect of the rigorous implementation of the IT principle, we have compiled the

Figure 8. Performance Chart. $\delta^{13}\text{C}$ -values as in Fig. 6. Here, the scale is based on reference gas injections only. Please note the enhanced scatter of the data.

Figure 9. Performance Chart. $\delta^{15}\text{N}$ -values as in Fig. 7. The scale is solely based on reference gas. Compared with Fig. 7 a larger scatter and some outliers are evident.

results of our QA standard based exclusively on our reference gas (Figs. 8 and 9). The data clearly exhibit a larger scatter than the data compiled including the IT calculations. For both $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$, the precision has increased by about 50%. It is also worth noting that a number of marked outliers are present in Fig. 9 that are not seen in Fig. 7. These outliers might have escaped our attention if the IT principle had not been included in the measurement and evaluation.

The composition of the N_2 gas inside our 50-L high-pressure cylinders has not changed much over the reported time span. There is a slope of 0.04‰/a in the solid line in Fig. 9 that is not present in Fig. 7. This slope probably represents a change in the N_2 reference gas. To explain the differences between the graphs we suspect a number of sources of error that all contribute to the observed dependence of the data:

- the pressure regulator on the tank is critical. Most regulators alter the isotopic composition of the dispensed gas at least temporarily, the size of the alteration being dependent on the gas itself and on the surfaces inside the regulator.³⁸ The same applies to the second type of GC regulators (Porter) in the interface. The alteration for the isotopic composition of CO_2 is in the sub-per mill range.
- The combustion and (or) the reduction tube can be contaminated with previous sample material giving rise to memory effects.
- The combustion efficiency may vary slightly thereby altering the isotopic composition.
- The efficiency of the reduction tube for scavenging excess oxygen and for reducing nitrous oxides may change with time.
- When diluting the CO_2 effluent, a change in isotopic composition may occur due to diffusion effects.³⁵

As long as the reference material suffers from the same deficiencies during preparation, the errors will at least tend to cancel out and the long-term data monitored by a QA standard will exhibit much better laboratory performance than with pure standard gas referencing.

D/H determination from water

Measurement of δD -values from water samples is carried out on a fully automated chromium reduction system at 900°C ('H/Device', Finnigan MAT, Bremen, Germany) directly coupled to the sample inlet of the dual inlet system of our MAT 252 isotope ratio MS.³⁹ The samples, positioned in a GC autosampler tray (AS200, CTC Analytics, Switzerland), are transferred to the hot injection port via a gas-tight syringe (Model 702, Hamilton, Switzerland). The quartz reactor (Finnigan MAT) is filled with chromium powder (100 mesh, Alfa Aesar, Karlsruhe, Germany). The reaction of water vapor with the hot chromium is almost instantaneous. The valve at the end of the reactor is opened after a preset time and the H_2 gas is transferred to an intermediate equilibration volume. Again, after a preset equilibration time (in order to avoid diffusive alteration of the isotopic composition of the hydrogen gas), the reactor valve is closed and the H_2 gas is passed to the sample volume of the dual inlet for measurement. The equilibration and transfer times are critical and must be under computer control.

We routinely run 60 analyses (~20 h) in a sequence with the laboratory reference water and the QA standard distributed in a prescribed loading list similar to that presented in Fig. 4. All data enter a spreadsheet for final calculation of δD -values (Fig. 10).

The data in column 3 (Fig. 10) are the original results as automatically transferred from the mass spectrometer PC. All samples are run in triplicate. The data treatment is more elaborate owing to the fact that multiple effects must be accounted for. First, we apply a memory correction (column 4) to the δD -values against the working gas. The magnitude of the correction is 1% carry over from the previous sample plus 0.2% from the sample before. The effect of the memory correction can be judged from the triplets where the difference to the precursor sample is large.

Next is the IT calculation, that is, replacement of the hydrogen gas reference by the laboratory standard water

samples in the run. The δ D-value (-66.45‰) of WWJ-1A (working water-Jena1A) has been established by direct measurement against VSMOW and SLAP samples (freshly opened ampoules) obtained from the IAEA in Vienna. Using this δ D-value and the actually measured average of WWJ-1A, the apparent working reference gas offset (-2.35‰, Fig.

10) is calculated according to:

$$\text{offset}_{\text{wgas}} = (-66.45 - \text{avg}_{\text{gwwj1}}) / (1 + \text{avg}_{\text{gwwj1}}/1000) \quad (4)$$

This offset is used to correct the raw memory corrected δ D-values and to provide a preliminary positioning relative to VSMOW (Eqn. (2)).

Figure 11. Performance Chart. $\delta^2\text{H}$ -values of the quality control standard RWB-J1 as a function of measurement time.

The next columns constitute a two-pass drift correction. The drift correction is necessary because the hydrogen reference gas in the dual inlet changes isotopic composition over time (a complete 60-sample sequence takes about 20 h). This is due to the fact that length and crimping of the capillaries are a compromise between CO_2 and H_2 work. To avoid back diffusion of isotopically altered gas into the variable volume, the capillaries would have to be twice as long for H_2 . Alternatively, a different crimp on reference vs. sample side could be used so that the reference could be operated at a much higher pressure. The magnitude of the drift depends on the filling state of the reference bellow volume at the beginning of the sequence. We have observed drifts of 3–5‰ in 20 h when starting with a full reservoir. Less reference gas results in larger drifts. Because the drift should follow an exponential function, we have implemented our analysis sequence with three reference water measurements in positions 34 to 36 and three more at the end of the sequence. The results for these reference water injections are used to correct the reference gas drift. A fine adjustment is made in column 13 (Fig. 10) that is only necessary for making the data mathematically consistent after drift correction (in the example shown the data are identical). The last correction involves scaling according to the observed scale contraction.⁴⁰ On average we have measured -425‰ instead of -428‰ for SLAP vs. VSMOW, hence all data are corrected by multiplying the difference from WWJ-1A by 1.007. The last two columns are the final δD -values on the VSMOW/SLAP scale and their precision.

^k Usually pure CO_2 gas is used for equilibration and a mass balance correction according to:

$$\delta_{\text{true}} = \delta_{\text{meas}} + \alpha x_{\text{gas}}(\delta_{\text{meas}} - \delta_{\text{gas}})/x_w \quad (5)$$

is applied (α = exchange fractionation factor, δ_{gas} is the $\delta^{18}\text{O}$ -value of the added CO_2 gas before equilibration and x_{gas} and x_w are the mole fractions of gas and liquid, respectively).

In our case, due to the small amount of CO_2 in the gas phase, the correction can be neglected down to about 50 μL H_2O . Equation (5) also applies to the equilibration of hydrogen gas with water.

In every 60-sample sequence we measure RWB-j1 (reference water B-Jena1) as a QA standard for generating the performance chart associated with the D/H procedure. Figure 11 shows the data as a function of measurement time. The overall precision of 0.83‰ vs. VSMOW is certainly acceptable. There is a tendency to more negative values at the end of the sequence that deserves further attention. During the short period of measurements this is not likely to be caused by a relative drift of our laboratory working waters. However, most of the internal precisions measured are better than 0.8‰ (see also Fig. 10). We attribute this finding to the fact that we do not determine the SLAP/VSMOW scaling factor for every sequence in contrast to frequent measurement of the H_3^+ factor. We started by using water samples with about 60‰ difference for implementing this correction. This difference turned out to be too small in relation to the measurement precision, leading to erroneous scaling factors. On the other hand, measuring water with about -400‰ δD in the same sequence affects the memory correction and the three samples following this negative water would have to be discarded. The potential for improving the performance chart precision to about 0.5‰ is within reach using the technique described.

Equilibration/irm-analysis for $\delta^{18}\text{O}$ determination

The ^{18}O abundance in water samples is usually measured with a modified $\text{CO}_2/\text{H}_2\text{O}$ equilibration technique. With a syringe we inject 400 μL water aliquots into 10-mL glass containers ('Exetainer') topped with a septum. Before water injection the glass vials are filled with a mixture of 0.5% CO_2 in helium.^k Equilibration takes place inside a 96-position autosampler rack held at 30°C ($\pm 0.1^\circ\text{C}$) that is part of the irm interface (GasBench II, Finnigan MAT). We operate the autosampler rack in two separate stages holding 48 sample tubes each. While one sequence of 48 samples is measured, the other batch of 48 samples is allowed to equilibrate for roughly 20 h. With this loading scheme we manage to have the system analyze samples almost continuously, i.e. 6 days per week.

Following equilibration, the sample vial is analyzed by piercing the septum with a double wall needle. The needle has a feed (He) and an exit (sample CO_2 in He). The flushing rate is approximately 0.3 mL/min. The sample gas flows over a Nafion[®] dryer and then through an injection loop from which the GC run (Poraplot Q) is started. From a single sample tube we inject about ten times. The ten CO_2 peaks are evaluated isotopically and the results are transferred to a spreadsheet for further data evaluation.

The measurement sequence is assembled as before, i.e. following a rigid structure determined by a dedicated loading list. Hence, the evaluation follows a similar pattern: a mean $\delta^{18}\text{O}$ is calculated for all CO_2 peaks from a single sample. The δ -values are referenced at first to co-injected CO_2 standard gas peaks that serve as a mediator between the samples. WWJ-1A water samples strategically located in the 48-sample sequence again serve to position the preliminary $\delta^{18}\text{O}$ -values onto the VSMOW scale. As in deuterium analysis, a light reference water sample is used to establish

$\delta^{18}\text{O}$ Performance of RWB-J1

Figure 12. Performance Chart. $\delta^{18}\text{O}$ -values of the quality control standard RWB-J1 as a function of measurement time. Analysis is made using an equilibration/irm-GC/MS system (GasBench II, Finnigan MAT).

the final scale normalization so that SLAP returns a value of -55.5‰ vs. VSMOW.

Figure 12 shows the long-term $\delta^{18}\text{O}$ -performance of our RWB-J1 QA reference water. Each point corresponds to a single RWB-J1 sample in a 48-sample sequence. Apart from the scatter of the individual sample measurements, the

¹ If the reference material has been determined ten times in the sequence and the precision of the measurement is 0.1‰ then the isotopic value of the reference is determined with an error of $t \cdot (0.1\text{‰}) / \sqrt{10} = 0.063\text{‰}$. The Student factor t (2.0 in our case) reflects the statistically low number of measurements.

overall precision of 0.14‰ also includes the error of the reference water determination in the respective analysis sequence.¹

Isotopic analysis of CO_2 in air

The isotopic composition of CO_2 in air is important for constraining the sources and sinks of this important greenhouse gas in the atmosphere. The average $\delta^{13}\text{C}$ -value of CO_2 in the atmosphere has remained fairly constant over millions of years at about -6.5‰ vs. VPDB. During the last 200 years anthropogenic input from fossil fuel burning has lead to a decline with an average $\delta^{13}\text{C}$ -value of about -8‰ at present. The decline continues at a rate of about $0.03\text{‰}/\text{a}$. The seasonal cycle of $\delta^{13}\text{C}$ varies with latitude and is a function of photosynthesis as well as human activity. At the South Pole the size of the cycling is about 0.05‰ (peak to peak) and increases to a maximum of 0.8‰ at high northern latitudes.⁴¹ These rather small isotopic signatures comprise multiple components including fossil fuel burning. Their measurement requires a high precision and accuracy analytical setup.

Our extraction line is schematically depicted in Fig. 13. From a Multiport valve the air passes through a capillary with a crimp, over a water trap at -70°C and a trap kept at -196°C . Here, CO_2 is frozen out at a pressure of about 400 mbar. The air is pumped through the pumping lines of the dual inlet system of our MAT 252 mass spectrometer.⁴² Sample CO_2 is measured directly from the sampling reservoir via a crimped capillary to the 'changeover valve'. The system is under full computer control for reliable timing and unattended operation. The precision of the system is aimed at and close to 0.01‰ $\delta^{13}\text{C}$ vs. VPDB and 0.025‰ $\delta^{18}\text{O}$ vs. VSMOW. It is very difficult to routinely prepare CO_2 from the primary reference materials (carbonates) across different laboratories at such levels of accuracy. Hence, the atmospheric CO_2 isotope ratio scales are refined scales that

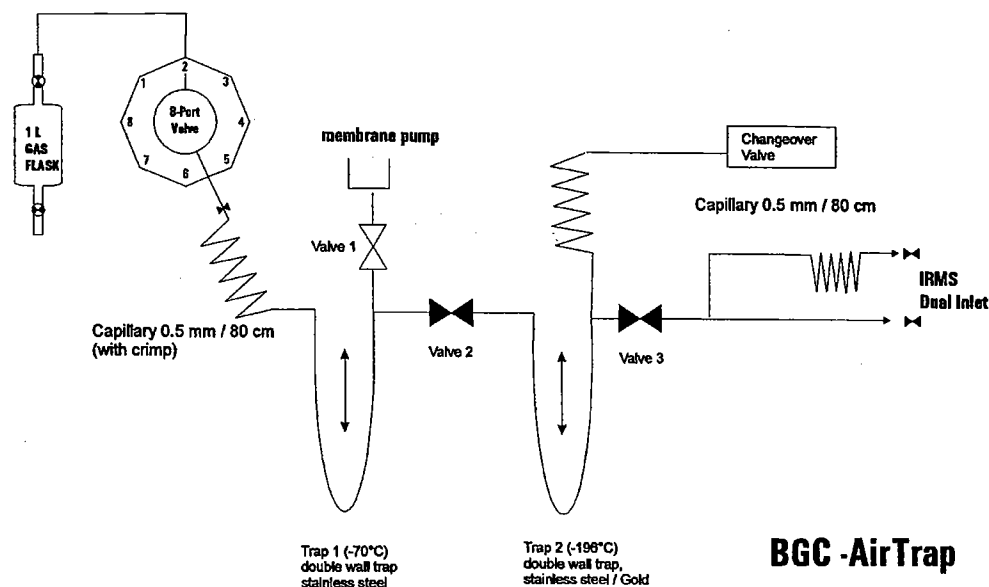

Figure 13. Schematic layout of the automated extraction system ('BGC-Airtrap') for high precision measurement of CO_2 isotope ratios in air.

use air samples and air in high-pressure cylinders as reference material. Consequently, the referencing in our system is made by a combination of permanently attached reference air (Multiport valve positions 1 and 2) as well as air in 1-L flasks that are exchanged routinely with other laboratories. The major problem here derives from the fact that gases are volatile. To keep them as reliable references requires a hierarchy of reference gases and a strategy that automatically detects mutual drifts in order to take corrective action. Without internal referencing high-precision measurement and international comparability of data would not be possible.

O₂/N₂ ratios in air

Complementary to the increase of CO₂ in the atmosphere there is a decrease of O₂. For every carbon atom burnt from fossil fuel one O₂ molecule is lost to CO₂. O₂ has sources and sinks that differ greatly from those of CO₂. Thus, by studying the decrease of O₂ i.e. measuring the O₂/N₂ ratio with high precision, a great deal can be learned about the global carbon cycle including the partitioning of sinks for CO₂ between the oceans and the land biosphere.

We have built a mass spectrometric inlet system for measuring O₂/N₂ ratios with a precision at the 5 perMeg^m level that is capable of monitoring small changes in atmospheric O₂ concentration. The system includes a 16-connection Multiport valve and an open split which is fed alternately from a sample and a reference gas, both switched on and off from a common transfer point, to a Delta⁺XL isotope ratio mass spectrometer (Finnigan MAT, Bremen, Germany). Referencing is made in a very similar fashion to that for CO₂ in air by measuring versus an air reference and implementing a multiple referencing hierarchy system. There is no international scale for this kind of work. Currently, consistency in the data is achieved by matching the scales of longer-term records measured by different laboratories. An intensive cooperation to overcome these limits to the comparability of data is under way by a group of laboratories involved in this type of analysis.

Correction of isobaric interferences

A review of referencing in isotope ratio measurements would not be complete without a discussion of the necessary corrections to the raw data. The precise measurement of isotope ratios is often hampered by interfering ion currents from other species hitting the same Faraday cup detectors. Among the most prominent examples are the contribution of

H₃⁺ on the mass 3 channel where δD is measured and the isobaric ¹²C¹⁸O¹⁷O⁺ ion current at the mass 45 position where $\delta^{13}C$ from CO₂ is determined. Here we intend to summarize some of the more important corrections. Further information for in-depth treatment is given in the cited literature.

¹⁷O correction for $\delta^{13}C$ determination

Using CO₂ gas, $\delta^{13}C$ cannot be measured independent of the oxygen isotope ratio unless the mass spectrometer used provides a working mass resolution of >52000. CO₂ gas contains a number of species with different masses ('isotopomers'). All combinations of stable isotopes are present, some of them very low in abundance. The list of isotopomers includes the major species ¹²C¹⁶O¹⁶O (*m/z* 44), ¹³C¹⁶O¹⁶O and ¹²C¹⁷O¹⁶O (*m/z* 45), ¹²C¹⁶O¹⁸O (*m/z* 46), as well as the minor species ¹³C¹⁷O¹⁶O and ¹²C¹⁷O¹⁷O (*m/z* 46), ¹³C¹⁷O¹⁷O, ¹³C¹⁸O¹⁶O and ¹²C¹⁷O¹⁸O (*m/z* 47), ¹²C¹⁸O¹⁸O and ¹³C¹⁷O¹⁸O (*m/z* 48) and ¹³C¹⁸O¹⁸O (*m/z* 49). When working in the natural abundance range of the isotopes the contributions of the minor species is small enough to be neglected. The ¹⁷O moiety at *m/z* 45, however, has a 7% contribution to the mass 45 ion current and must always be corrected for when determining $\delta^{13}C$ -values.

The square-root formula for correcting the ¹⁷O contribution to the 45/44 ratio is sometimes referred to as the Craig correction. Harmon Craig⁹ assumed a tight relationship between ¹⁷O and ¹⁸O with a fractionation coefficient λ of 0.5 exactly and devised a simple correction expression:

$$\delta^{13}C = 1.0676^{45} \delta_{\text{meas}} - 0.0338 \delta^{18}O \quad (6)$$

The numerical values in this expression are the ratio terms ⁴⁵R/¹³R and ¹⁷R/(²¹³R) of the reference gas evolved from the PDB standard as determined or used by Craig. As explicitly pointed out in the paper these numerical values do not apply to other standards and must therefore be used with great care.ⁿ Moreover, the average relation of ¹⁷O and ¹⁸O on earth (Craig equation: (¹⁸R_{sa}/¹⁸R_{st})^λ = ¹⁷R_{sa}/¹⁷R_{st}) cannot be described exactly using a fractionation factor λ of 0.5. Instead, 0.516⁴³ seems to be closer to the correct value for λ .^o The debate about the exact relationship found on earth is ongoing with new experimental values of 0.524 and 0.528 reported for λ .^{44,45}

PDB has been superseded by VPDB and the absolute ratios of the reference scale have been refined. In order to keep literature data consistent, Allison *et al.*⁴⁶ have compiled a recommendation for the ¹⁷O correction that keeps the 0.5 fractionation factor and provides exact values for all ratios involved. On the other hand, Santrock *et al.*⁴⁷ have shown in a H₂O/CO₂ equilibration experiment that data for $\delta^{13}C$ were not independent of the $\delta^{18}O$ -values of the equilibration water when using the Craig equation. The correction proposed includes a fractionation factor of 0.516 and an iterative correction procedure because the exact equations cannot be solved analytically for ¹³C. The dispute is not yet settled. Whatever correction algorithm is chosen (the mass spectrometer software should provide a choice), it is important to make sure that the reference gas isotope ratios

^m 1 perMeg is 0.001‰ in δ -units. It corresponds to a concentration change of 0.2 ppm O₂ in air.

ⁿ The numerical values in Eqn. (6) may be treated as variables. In this case, a set of water equilibration experiments with CO₂ gas that has identical carbon but different oxygen isotope ratios and vice versa can be made to determine the values of these variables. A correction based on these values will result in correct $\delta^{13}C$ -values irrespective of the exact knowledge of the oxygen isotope fractionation factors (T.B. Coplen, private communication).

^o If the kinetics of the reactions causing isotopic fractionation are governed entirely by the respective zero point energy differences it can be shown that $\lambda = [(\mu_{16})^{-0.5} - (\mu_{17})^{-0.5}] / [(\mu_{16})^{-0.5} - (\mu_{18})^{-0.5}]$, with μ being the reduced mass. Using exact masses for a C-O bond the result is $\lambda = 0.5273$ which represents an upper limit for kinetic processes. In equilibrium processes, the value for λ can be as high as 0.531.⁴³

used in the calculations are consistent with the $\delta^{13}\text{C}$ -values assigned to the primary reference material.

Please note that the correction is only valid for CO_2 from terrestrial sources, not for tracer studies. In addition, there is a strong ^{17}O anomaly in ozone in the stratosphere that affects other trace gases including CO_2 sampled from the atmosphere.

H_3^+ correction

Inside the ion source of the mass spectrometer ions are produced from neutral molecules m by 70 eV electron impact according to:

The molecular radical cation m^{+} is produced in a variety of excited states. If the internal energy is high enough, molecular ions may decompose in a unimolecular decay reaction resulting in a daughter ion and a neutral (mostly a radical) giving rise to the observed mass spectrum. Another process can take place when ions within the ion source hit a neutral molecule. In this case, secondary ions may be formed via ion/molecule reactions. The formation of H_3^+ follows such a mechanism:

The reaction constant of Eqn. (8) is proportional to the number of both H_2^{+} and H_2 . For a given sensitivity of the mass spectrometer, the number of H_2 molecules is proportional to the H_2^{+} ion current, hence:

$$[\text{H}_3^{+}] = k \times [\text{H}_2^{+}]^2 \quad (9)$$

and the ratio $[\text{H}_3^{+}]/[\text{H}_2^{+}]$ is a linear function of the mass 2 ion current ($= k \times [\text{H}_2^{+}]$). The proportionality constant k is called the ' H_3^+ factor'. It is conveniently expressed in (ppm/nA) units.

In practice, the ion source is tuned to a large acceleration field across the ionization volume in order to minimize the time for the ion/molecule reaction (8) and hence suppress H_3^+ production. The H_3^+ factor is measured by observing the mass 3 ion current as a function of mass 2 ion intensity; a linear function is fitted through the data points. The correction involves a simple point-to-point subtraction of a linear portion of the mass 2 ion current from the signal observed at mass position 3. This is usually performed using the (clean) working reference gas. In particular, when helium carrier gas techniques are used, there may be other sources of non-linearity of m/z 3/2 including isobaric interference of He^{2+} ions at m/z 2 that should be studied and evaluated separately or traces of hydrocarbons that constitute a different source for H_3^+ ions.

There are other means of correcting the contribution of H_3^+ to the measured 3/2 ion current ratio.⁴⁰ The simplest correction is no correction at all which will obviously result in differences between reference and sample that are too small. Provided there are several isotopically known samples interspersed with the analyte material, a correction can be deduced from the results of these that may fully cover the requirements. As a general guideline, however, we feel that all effects should be studied and quantified as precisely

as possible in order to apply a valid correction and keep track of the details.

^{18}O correction for $\delta^{34}\text{S}$ determination using SO_2 gas

As for carbon isotope ratio analysis, the ion currents of SO_2 are influenced by the oxygen isotopes. In order to extract $\delta^{34}\text{S}$ the $^{32}\text{S}^{16}\text{O}^{18}\text{O}^{+}$ contribution to the mass 66 ion current (about 8.3%) needs to be taken into account. Unfortunately, there is no independent measurement of the other oxygen isotope, ^{17}O , which would enable a strategy similar to that for carbon isotope ratios. Instead, the established correction aims at keeping the oxygen isotopes in the sample and the reference SO_2 identical. In this case, the measured δ^{66} -values can be converted to $\delta^{34}\text{S}$ -values according to:⁴⁸

$$\delta^{34}\text{S} = {}^{66}\delta_{\text{meas}} + 2^{18}\text{R}/^{34}\text{R} \times ({}^{66}\delta_{\text{meas}} - \Delta\delta^{18}\text{O}) \quad (10)$$

In Eqn. (10) $^{18}\text{R}/^{34}\text{R}$ refers to the isotope ratio values of the standard gas and $\Delta\delta^{18}\text{O}$ is the ^{18}O difference between sample and reference SO_2 . Since these values cannot be measured independently in a simple way the expression $^{18}\text{R}/^{34}\text{R}$ is usually computed using the ratio values of VSMOW ($^{18}\text{R} = 0.0020052$, see Table 1) and VCDT ($^{34}\text{R} = 0.0441509$) and $\Delta\delta^{18}\text{O}$ is set to zero. Hence, the correction simply involves multiplying ${}^{66}\delta_{\text{meas}}$ with 1.091 for obtaining $\delta^{34}\text{S}$.

The simplification of Eqn. (10) applies strictly only when the oxygen in both sample and reference SO_2 are isotopically identical ($\Delta\delta^{18}\text{O} = 0$) and equal to VSMOW and the sulfur is isotopically equal to VCDT. Hence, this can only be regarded as a first-order correction. Fortunately, small errors in the adopted ratios do not alter the analytical result significantly. A difference in ^{18}O content in terms of $\delta^{18}\text{O}$, however, translates into an error of the analytical result that is 9% of the $\Delta\delta^{18}\text{O}$ -value.

Due to the 'stickiness' of SO_2 on surfaces, further corrections are necessary and recommended.⁴⁹ A systematic scaling factor of about 1.035 between sulfur measurements using SF_6 and others using SO_2 has been observed by many laboratories. The simplest overall correction is scaling the measured and first-order corrected SO_2 data with known isotopic compositions of reference material prepared together with the unknown samples. For sulfides, IAEA-S-2 (+22.66‰ VCDT) and IAEA-S-3 (−32.30‰ VCDT) provide good references for the scaling exercise. For analyzing barium sulfates, IAEA-SO-5 (+0.49‰ VCDT) and IAEA-SO-6 (−34.18‰ VCDT) will serve the purpose. Please note that the latter two values are provisional.^h

For IRMS techniques, where the SO_2 reference gas comes from a high-pressure cylinder, calculation of data should be made exclusively in terms of ${}^{66}\delta_{\text{meas}}$ -values up to the point where the reference is a sample processed exactly as the other samples (identical treatment again). Only then is the oxygen isotope signature similar enough to use the first-order correction given above.⁵⁰

Further corrections

Drift corrections

During analysis of a series of measurements one often observes a drift of the results as a function of time (or sample number). Drifts can have multiple causes including isotopic change of

the reference gas in the dual inlet system during an analysis sequence, build up of water or other contaminants during analysis, changing conditions of the mass spectrometer for instance following a fresh pump down of the vacuum system, deterioration of ion source conditions and many more. Many of these causes can and should be fixed by changing the conditions of the analysis. However, this can only be accomplished reliably when the overall design of the analytical sequences allows easy detection and provides means for correction of the drifting results. The design rules are simple: A sufficient number of identical samples are interspersed with the analyte samples and used to correct the drift. For an example of drift correction please refer to the spreadsheet in the hydrogen isotope analysis section (Fig. 10).

Linearity corrections

Similar to drift in time is a drift with size, i.e. the measured ratio is a function of the size of the sample (or a reagent). Commonly observed size or linearity effects are the dependence of the measured ratio of the analyte gas on the size of the major ion beam ('pressure effect'), the observed fractionation of hydrogen isotopes as a function of the amount of reduction reagent used, or the dependence of measured $\delta^{18}\text{O}$ -values on temperature during an equilibration experiment. The first and obvious choice is to eliminate the causes of the linearity problems by improving temperature stability or reducing the dwell time of the ions in the high-pressure region of the ion source. This is often successful for reducing the size of the effect. However, a small fraction will almost always remain and thus will have to be corrected for. The general correction strategy is similar to the one described above: A sufficient number of known samples are measured together with the analyte samples. In this case the amount of material is varied in order to detect the size of the required linearity correction.

Correcting cross contamination in dual inlet measurements (η -correction)

Following a switching action of the 'changeover valve' from one gas to the other a delay time ('idle time') is necessary to await complete exchange of the gases in the ion source. Depending on the gas this can be rather short (~ 4 s) or it may take up to several minutes for a complete replacement. Gases like H_2 , N_2 , SF_6 or N_2O have little surface activity and, hence, are pumped away fast whereas SO_2 and CO_2 can take considerably longer to exchange completely. The time depends on the material of the sputtered surfaces, on the sensitivity of the instrument, on the tightness of the ion source design and other parameters. The true δ -value can be calculated from the measured value according to:⁵¹

$$\delta_{\text{true}} = \delta_{\text{meas}} / (1 - 2\eta - \eta\delta_{\text{meas}}/1000) \quad (11)$$

with η describing the cross contamination affecting the background of the subsequent measurement. (Please note that Eqn. (4) in Ref. 51 is cast in absolute terms of δ , not in‰ 'units'). Meijer *et al.*⁵¹ also suggested a correction strategy which comprises (1) experimental determination of the cross contamination parameter η by introducing natural isotope abundance and enriched gas followed by (2) application of Eqn. (11) to the raw analytical results. For CO_2 , the numerical

value for η mostly ranges between 0.001 and 0.01. In some cases (when the ion source is rather tight, the sensitivity is high and the sputtered surface area is large) the η correction can be as large as 1‰ for $\delta^{13}\text{C}$ in CO_2 when the isotopic difference exceeds 40‰.

An alternative and recommended correction for cross contamination is scaling to precisely known (large) differences of reference materials as is routinely done in hydrogen and oxygen isotope ratio analysis by scaling to the SLAP/VSMOW difference. Besides hydrogen and oxygen isotope ratio determination this scale normalization has proven mandatory for sulfur (measured as SO_2) and might also turn out to be required for carbon, in particular when the measured isotopic differences are large and (or) the precision requirements are high.

Reporting of experimental data

Isotope ratio data often enter into a multidimensional puzzle from which further conclusions are drawn. This is the case in almost any carbonate or precipitation study; it is obvious also in CO_2 in air analyses. Sometimes isotope ratio data are valued by other researchers in a way that the original author had not anticipated. As a consequence, isotope ratio data reported in the scientific literature should be presented together with the necessary context that accompanies the pure number. Wherever the source of the scale that was used for referencing experimental values to an international standard may have arisen from, the procedure should and must be described.

For instance, most combustion analyses are calibrated with NBS-22 oil using a published $\delta^{13}\text{C}$ -value of, for example, -29.74‰ on the VPDB scale. This value, however, has been revised a number of times; the latest revision to -29.78‰ happened only recently.¹ Thus, when published data are compared with other data reported vs. VPDB based on a different value or even based on a different material, adjustments can be made, provided the basis of the scale is clear. In addition to the final δ -values, precision ($\equiv 1\sigma$, standard deviation) as well as sample preparation and measurement techniques should accompany the data in order to judge the relative merits of published data.

Similarly, for reporting $\delta^2\text{H}$ -values of substances other than water, it is recommended that the author's measured $\delta^2\text{H}$ of NBS-22 oil, NBS-30 biotite, IAEA-CH-7 polyethylene foil, or other internationally distributed reference material be reported, as appropriate to the analytical method. Please note that normalization to the -428‰ difference of SLAP and VSMOW, as is mandatory for water analysis, requires the availability of new internationally distributed reference materials. The normalization procedure should be stated in the author's report.

For reporting $\delta^{18}\text{O}$ -values of substances other than water or carbonates (including the measurement of pure CO_2 gas), it is recommended that the author's measured $\delta^{18}\text{O}$ of NBS-28 quartz, NBS-30 biotite, NBS-127 barium sulfate, atmospheric oxygen or other internationally distributed reference material be reported, as appropriate to the analytical method. The $\delta^{18}\text{O}$ scale should be normalized such that the $\delta^{18}\text{O}$ of SLAP reference water is -55.5‰ VSMOW exactly, and so stated in the author's report.

CONCLUSIONS

We have described some of the recently developed techniques for referencing stable isotope ratio values in routine operation in our laboratory. The quality control for long-term accuracy is built into the daily cycles. Performance or quality charts help detect errors in high-precision referencing early and provide means for correction. It is common practice in many laboratories to treat sample and reference material in an identical manner. We propose to adopt this practice as the general principle guiding the positioning of measured isotope ratios on international scales.

Acknowledgements

We would like to thank Beate Rothe, Stefan Braeunlich and Heike Geilmann for their excellent performance of most of the analyses described. The students and post-docs in our institute have generously provided samples and weighed or filled them in for measurement. Elizabeth W. Sulzman and Charles B. Douthitt have made helpful comments and corrections to the draft manuscript. We are grateful to T. B. Coplen for his critical and very helpful comments to the first draft of this manuscript in a difficult time and for promoting publication by acting as a sponsor referee for this paper.

- Spreadsheets are the perfect tool for establishing the data analysis schemes and procedures. They can, however, become cumbersome with time, in particular when information from the past must be retrieved from a large pile of data and the criteria for the retrieval have changed. Once the procedures in the laboratory have become stable and mature the use of spreadsheet should therefore be replaced by a database system that handles the sample flow and reporting as well as the retrieval of the results. An example of such a LIMS system has been developed by T. B. Coplen, USGS, Reston, and is described in T. B. Coplen, A Guide for the Laboratory Information Management System (LIMS) for Light Stable Isotopes, Versions 7 and 8, US Geological Survey, Open-File Report 00-345, 121 pp.

Although high-precision isotope determinations are routine in many areas of natural science, the instrument principles for their measurements have remained remarkably unchanged for four decades. The introduction of continuous-flow techniques to isotope ratio mass spectrometry (IRMS) instrumentation has precipitated a rapid expansion in capabilities for high-precision measurement of C, N, O, S, and H isotopes in the 1990s. Elemental analyzers, based on the flash combustion of solid organic samples, are interfaced to IRMS to facilitate routine C and N isotopic analysis of unprocessed samples. Gas/liquid equilibrators have automated O and H isotopic analysis of water in untreated aqueous fluids as complex as urine. Automated cryogenic concentrators permit analysis at part-per-million concentrations in environmental samples. Capillary gas chromatography interfaced to IRMS via on-line microchemistry facilitates compound-specific isotope analysis (CSIA) for purified organic analytes of 1 nmol of C, N, or O. GC-based CSIA for hydrogen and liquid chromatography-based interfaces to IRMS have both been demonstrated, and continuing progress promises to bring these advances to routine use. Automated position-specific isotope analysis (PSIA) using noncatalytic pyrolysis has been shown to produce fragments without appreciable carbon scrambling or major isotopic fractionation, and shows great promise for intramolecular isotope ratio analysis. Finally, IRMS notation and useful elementary isotopic relationships derived from the fundamental mass balance equation are presented. © 1998 John Wiley & Sons, Inc., Mass Spectrom Rev 16, 227–258, 1997

I. HIGH-PRECISION MASS SPECTROMETRY

Mass spectrometry (MS) is best known among chemists as one of the most important analytical techniques for the characterization of molecular structure and amount, elemental composition and spatial arrangement (Burlingame, Boyd, & Gaskell, 1996). Remarkably, among a large cross-section of biomedical, biological, and other natural scientists it is better known as a tool to reveal the origin, genesis, or state of complex systems through high-precision isotope ratio measurements. Careful determination of isotope abundances reveal this other dimension of matter, which often is not available from structural or quantitative studies.

Soon after the “natural” abundances of the elements were determined, variations linked to material sources were noticed, and systematics were described, starting with Nier and Gulbransen’s 1939 observation that the concentration of ^{13}C is greater in carbonates than in organic carbon (Nier & Gulbransen, 1939). Isotope variation due to natural processes is now known throughout natural science and has provided important data on phenomena as diverse as respiration in trees (Dawson & Ehleringer, 1993), dietary studies of ancient humans (“paleodietary reconstruction”) (Stott & Evershed, 1996), and contemporary animals (e.g., seal lion foodwebs (Hobson et al.,

1997), nitrification rates in forests (Starle & Hart, 1997), biodegradation (Aggarwal et al., 1997), and the climate history of the earth (Schoell et al., 1994). In ecology and biogeochemistry alone, two volumes (Ehleringer & Rundel, 1988; Ehleringer, Hall, & Farquhar, 1993) and at least one meeting (Griffiths, 1996) devoted to applications of high-precision isotope measurements have appeared in the last few years. Isotope ratio MS (IRMS) has penetrated areas of biological science to a greater degree than organic mass spectrometry. In addition to studies of natural variability, high-precision isotope measurements facilitate a number of tracer techniques in the biomedical sciences, including the doubly labeled water method for energy expenditure (Schoeller et al., 1986), protein turnover studies (Chapman et al., 1990), fat metabolism (Brenna, 1997), and a range of breath tests with the potential to revolutionize clinical diagnostic testing (Ghoos, Rutgeerts, & van Trappen, 1995).

The early history of MS was dominated by physical measurements to establish the nominal, terrestrial isotopic abundances of the elements. The early parabola method resulted in the discovery of two forms of Ne in 1911 by J. J. Thompson, with the recognition in 1919 that these ions were isotopes, using the first mass spectrograph (Aston, 1942). The latter event is arguably the first gas isotope ratio mass spectrometry (IRMS) experiment. Determination of the isotopic abundances of the elements was an application so dominant that one of its most productive participants, F. W. Aston, is said to have predicted the demise of MS as a field of research once the isotopic abundances of all the elements had been determined (Svec, 1985). It was, however, difficult to foresee the utility of high-precision isotope ratios as clues to a sample’s origin or history, or the importance of isotopes as artificial tracers. Even in the 1930s, before the isotopic abundances of all the elements had been established, the MS analysis of stable isotopes as tracers was yielding important breakthroughs in the bio-sciences (Clarke, 1948).

Natural abundance applications for the most part require the high-precision techniques introduced in the late 1940s; these techniques dominated IRMS for four decades. They focused initially on the analysis of bulk environmental materials of high chemical complexity such as plant or petroleum reduced to simple analysis by combustion to CO_2 or conversion to N_2 or H_2 . Analysis of chemically pure materials was much more common for compounds that occur in relatively pure form in nature such as water, because off-line separation is a time-consuming affair fraught with the risk of contamination and subtle isotopic fractionation. Much less common is the even more cumbersome analysis of intramolecular isotope ratios, which require the manual isolation of individual positions in a molecule following chemical isolation, all in an isotopically representative and uncontaminated form.

Fundamental changes in inlet systems introduced to multicollector IRMS in the 1980s, permitting detailed analysis of complex mixtures, are now fueling a revolution in IRMS, in the same way that analogous innovations did for organic MS in the 1950s and 1960s (Gohlke & McLafferty, 1993; McLafferty, 1997). High-precision "compound-specific isotope analysis" (CSIA), coupling GC separation to IRMS, ushered in dramatic improvements in sensitivity and analysis speed for chemically pure analytes and complex mixtures. Referred to generically as continuous flow (CF) instruments, their commercial appearance around 1990 precipitated a dramatic increase in research on instrumentation and methods in high-precision isotope ratio mass spectrometry. Recent advances also offer the promise of automated high-precision position-specific isotope analysis (PSIA), a field that has seen remarkably little experimental advancement in spite of the ubiquity of intramolecular isotopic variability in nature.

It is our purpose to review the current status of CF-IRMS instrumentation. After a brief review of classical IRMS instrumentation, we focus on CF introduction systems, which facilitate rapid, bulk, compound-specific, and position-specific isotope analysis. We close with a review of some basic calculations that are essential for the manipulation of high-precision isotope ratio results.

A. Isotope Ratio Mass Spectrometry (IRMS)

1. High-Precision

All mass spectrometers can measure isotope abundances in one way or another. The distinguishing characteristic of isotope ratio mass spectrometers (IRMS) is a measurement at *high-precision*, which is defined generally as a standard deviation in the range of 4–6 significant figures. High-precision isotope measurements by MS are possible for all polybaric elements of the periodic table by one of three instrument types, generally referred to as gas IRMS, *thermal ionization MS* (TIMS) for metals, and *static gas* or *noble gas* instruments. The designation IRMS usually refers to the gas-source machine that is dedicated to the analysis of light elements, and frequently the term *gas IRMS* (GIRMS) is used to distinguish it from TIMS. IRMS operates on different principles than TIMS or noble gas machines, which are outside the scope of this review. A recent review documenting commercial vendors for all these instruments has appeared (Newman, 1996).

High-precision is accomplished at the expense of flexibility. IRMS instruments accept the analyte in the form of one of a limited number of gases, which must be isotopically representative of the original sample. $^{13}\text{C}/^{12}\text{C}$, $^2\text{H}/^1\text{H}$, $^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$, and $^{34}\text{S}/^{32}\text{S}$ analyses are performed through analysis of the pure gases of CO_2 , H_2 , N_2 , N_2O , NO , O_2 , CO , and SO_2 or SF_6 ; for CF applications, these

FIGURE 1. Diagram of a generic isotope ratio mass spectrometer, not including inlets. A tight electron impact ion source efficiently generates positive ions that are mass-analyzed by a single magnetic sector. Multiple Faraday cups permit simultaneous and continuous monitoring of the analyte major isotopomer masses in a split flight tube for hydrogen or for other gases. Universal collectors with a central narrow cup and two outer wider cups are used for capturing higher mass gases such as CO_2 and N_2 .

gases will usually be in He carrier gas. These gases are the only ones that are admitted to the ion source of the IRMS.

The mass spectrometer design was developed by A. O. Nier in the 1940s and is the basis of modern instruments (Nier, 1940; 1947; Murphey, 1947; McKenney et al., 1950). A diagram of the basic instrument is presented in Fig. 1, which shows the ion source, single magnetic sector, and multiple collectors for the various isotopomers. Several features distinguish the components of the IRMS instrument from mass spectrometers used for structural studies, which we refer to as *organic MS*. These features are driven by the high-precision aspect of IRMS that requires that the detection probability be maximized to optimize counting statistics. In effect, the flexibility of organic MS is sacrificed to tailor the IRMS to very limited but high-performance measurements. An excellent detailed discussion of the design and theoretical performance of the ion source, ion optics, mass analyzer, and collectors for an IRMS is available (Prosser, 1993).

2. Ion Source and Dual Inlet

The IRMS employs an electron impact (EI) ion source specifically tailored to maximize ionization probability. Organic MS EI ion sources are designed so that the analyte stream passes through the electron beam once, where analyte molecules are either ionized or pass out of the source and are pumped away. Ionized molecules are rapidly accelerated into the analyzer section before collisions can take place. Reactive collisions that result in ions of weights greater than the analyte molecule would complicate EI

mass spectra greatly, because the highest mass ion would no longer be the putative molecular ion, and spectra would be dependent on ion source pressure. In addition, ion sources would require frequent cleaning, because reactive higher molecular weight products are more prone to condensation than lower molecular weights. Effectively, organic EI sources are nearly collisionless and are referred to as "open" sources.

The IRMS ion source is referred to as a "tight" source, because the goal is to contain analyte molecules until they are ionized to maximize ionization probability. Analyte gas molecules undergo many collisions with each other and the interior source walls prior to electron impact ionization, and nascent ions undergo collisions with neutral analyte molecules. In this regard, the IRMS EI source is much more like an organic chemical ionization (CI) source, which depends on collisions to facilitate proton exchange or other processes. Ion-molecule reactions do occur for IRMS gases when there is a source of hydrogen in the ion source. The most common source is the $H_2-H_2^+$ reaction that results in the formation of H_3^+ , which is an important interference in hydrogen analysis. The high collision rate of the EI source is one of the principal reasons why the analyte must be converted to a low molecular weight, relatively unreactive gas, and why hydrogen must be excluded whenever possible.

The ion source produces a 70-eV electron beam, collimated by small source magnets, for the EI ionization of gas molecules. The tight source produces high ion efficiencies of about 1 ion per 10^3 molecules that enter the source. This efficiency compares to that of about 1 ion in 10^6 molecules for the conventional open organic ion sources that are used for structural chemical analysis. This sensitivity advantage is usually even greater on a per mol analyte basis, because analyte molecules must be converted to an acceptable analysis gas. For instance, each molecule of methyl stearate introduced to an organic MS has a single chance for ionization. IRMS analysis requires conversion of the 19-carbon methyl stearate molecule into 19 molecules of CO_2 , each of which has an independent probability of ionization in the IRMS. Differences in ionization energies and cross-sections, and extent of fragmentation exist between large organic molecules and CO_2 . Nevertheless, an advantage of an order of magnitude in sensitivity can be expected in our example.

From this example, and in contrast to organic MS, it can be seen that it is inappropriate to quote "detection limits" for IRMS in the classical analytical chemical sense. Rather, the minimum amount of analyte required for analysis is appropriately expressed as mol of analyte element (e.g., C, N, etc.) required to yield a specified precision. For some elements, such as C, the *weight* of analyte is closely related to the molar mass; thus, it is

simplest to express lower analytical limits in terms of analyte mass. For example, the lower limits of analysis for an amino acid of molecular weight 100 and for a protein of molecular weight 100,000 are both approximately 10 ng, or about 1 nmol C.

Collisions in the ion source interact in a complex way to produce a well-known nonlinear dependence of ion current ratios with source pressure. The electron beam-collimating magnets exert a mass-dependent influence on the flight path of nascent ions as they are accelerated out of the source. The precise region within the source from which ions escape is related to source pressure; hence, the degree of flight path influence is related to source pressure (Kirshenbaum, 1951). It is easy to show that a plot of ion current ratio vs. m/z 44 intensity, I_{45}/I_{44} vs. I_{44} for carbon analysis, has a linear dependence on pressure that can be essentially eliminated by using He carrier gas to buffer analyte concentration changes (Tobias & Brenna, 1996). In the absence of a buffer gas, high-precision and accuracy demand that sample and standard be analyzed at the same pressure, which should be as constant as practical.

The dual-inlet system was first introduced in 1947 by Murphey (1947) for the analysis of gas diffusion rates, and it was soon incorporated into the classic analytical IRMS instrument design of McKinney et al. (1950). That design is a landmark usually taken to be the birth of high-precision IRMS. Modern dual-inlet systems are computer-controlled with adjustable welded-metal bellows in which sample and standard gas are stored. The pressures of the bellows are matched so that both gases enter the ion source at the same flow rate and pressure. In addition, the capillary used to feed the gases into the source is crimped to set flow resistance and permits flow rates to be matched. Through the use of automated valves, the sample and standard gases can be alternately delivered into the IRMS while the other volume is depleted and vented to waste at a matched rate to maintain equivalent pressures in both bellows.

3. Analyzer

Mass resolution is sacrificed to optimize stability and transmission, which are the two most important features for IRMS mass analysis. The IRMS analyzer section starts with an entrance slit that is typically of fixed width and gives a working resolution of about $m/\Delta m = 100$, which is sufficient to separate the masses of interest while maintaining maximum transmission. Ions are extracted and accelerated out of the ion source at 2–10 keV, collimated into a beam by electrostatic lenses, and deflected electrostatically into a magnet with a field of around 0.75 tesla. The analyzer is always a single magnetic sector, which is sometimes a permanent magnet, requiring that mass adjustments be made by adjusting the accelerating voltage.

A uniform magnetic field is required to produce multiple well-defined ion beams emerging toward the detectors. High mass resolution is not required and, thus, electric sectors are uncommon.

In the particular case of CF analysis of HD entering the ion source in a stream of He, high-performance mass analysis is desirable. High-abundance sensitivity is useful to separate the tail of the very large He peak at m/z 4 from the adjacent HD peak at m/z 3. One manufacturer introduced such an instrument in 1995 that can comfortably make this analysis; this instrument will be detailed in the hydrogen section below.

4. Detection and Data Acquisition

The majority of organic MS instruments employ electron multipliers (EM) for ion detection, with the most prominent exception being trap-type instruments such as Ion Cyclotron Resonance (Marshall & Verdun, 1990) and a recently reported advance in rf ion traps (Soni et al., 1996). IRMS instruments are probably the only analytical gas source mass spectrometers in commercial production at this writing that employ faraday cups (FC) for ion detection. Multiple cups are in routine use, one for each ion beam of interest, to maximize dwell times and eliminate the need for peak-jumping. Simultaneous measurement also improves precision dramatically, because it eliminates variability in analytical conditions that cause correlated changes in signal intensity such as filament brightness. Deep cups with secondary electron suppressers capture analyte ions and the secondary electrons emitted upon impact of high-energy ions onto the metal surface. Dedicated amplification electronics are required for each mass channel. FCs are generally less sensitive than EMs, but are superior for IRMS because (1) the high count rates required for high-precision place IRMS signals in the normal detection range for FCs, but would rapidly damage EMs; (2) FCs linearly detect very large ion currents without gain adjustments; (3) they are highly stable; and (4) with the low atomic weight elements used in IRMS, they have very long lifetimes that are measured in decades.

Amplification of signal at the FC is accomplished by dedicated circuits mounted in close physical proximity to the detectors. The feedback amplifiers are usually highly shielded, sometimes held under vacuum, and are made with high performance resistors to yield amplification factors corresponding to the approximate isotopic abundance in nature. For example, the feedback resistors for H₂ and HD are in the nominal ratio 1:1000 and, when digitized, produce signals that have heights about 1:0.3, corresponding to the 150 parts-per-million abundance of D compared to H, after correcting for the dual probability of D appearance in HD. Matching of signals is critical for the high-precision comparisons central to IRMS data analysis in

dual inlet analysis, because there is no He carrier gas to equalize pressures. It is much less important for continuously varying analyte signal in CF analysis, except for H analysis. Poor signal matching is the major factor why signals that diverge significantly from natural abundance (in tracer experiments, for example) commonly yield poor precision and accuracy.

The dual-inlet data stream is extraordinarily straightforward. A sample from each inlet is admitted to the IRMS, the signal is allowed to stabilize, and data are collected at a plateau level. After a preset measurement time, inlets are switched and the cycle is repeated several times. Ion current ratios are converted to isotope ratios using the delta notation suggested by Urey in 1948 (Hayes, 1983), shown as follows for the specific case of carbon:

$$\delta 45 = \left(\frac{R_{SPL} - R_{STD}}{R_{STD}} \right) \times 1000 = \left(\frac{R_{SPL}}{R_{STD}} - 1 \right) \times 1000;$$

$$R_x = \frac{[45]}{[44]}, \quad (1)$$

where [45]/[44] is the ion current ratio, and $\delta 45$ includes contributions from both ¹³C- and ¹⁷O-substituted CO₂. For carbon, an expression for ¹³C/¹²C is normally desired, and correction procedures have been devised to use the mass 46 signal, which is primarily representative of the ¹²C¹⁸O¹⁶O species, and the correlation in nature between ¹⁸O and ¹⁷O, to convert $\delta 45$ to $\delta^{13}\text{C}$, relative to the working standard (Craig, 1957; Santrock, Stanley, & Hayes, 1985). A final adjustment converts the sample isotope ratio into terms relative to the international standard Pee Dee Belemnite, in parts "per mil" or "per mille" (‰). This notation has two advantages. First, it emphasizes that the high-precision component of the measurement is relative to a standard, rather than an absolute measure. Second, isotopic fractionation in nature is subtle, yielding changes in the fourth significant figure and beyond; the $\delta^{13}\text{C}$ notation eliminates the leading digits common among nearly all but artificially enriched samples and focuses on changing digits. We return to isotope notation later.

Analogous calculations are performed for CF data, except that the ion current ratios are normally derived from peak areas rather than plateau regions. The CF data stream consists of a time array and two or three signal arrays, which are most analogous to selected ion monitoring chromatographic traces in organic MS. Signals must be digitized to about 20 bits (>10⁶) to retain sufficient precision, and suitable precisions are available on modest cost chromatography data acquisition boards designed to record data from a flame ionization detector (FID), and offer effective duty cycles of greater than 95%.

5. Isotopic Standards

We briefly mention the existence of international isotopic standards for the IRMS elements because more complete discussions can be found elsewhere (Ehleringer & Rundel, 1988). Standards are often calibrated by several laboratories in "round-robin" or "ring" tests, where many laboratories blindly analyze carefully prepared aliquots (for example, see (Schoell & Faber, 1983)). A 1987 *Mass Spectrometry Reviews* article lists IRMS international standards for H, C, N, and O complete with references (Table I of (Hachey et al., 1987)). Many of the primary standards are available today and can be obtained by individual laboratories for use as calibrants for day-to-day working standards.

For C, N, O, and S, a single international standard is normally adequate for isotope ratio calibration of naturally occurring samples. Hydrogen is somewhat unique in its requirement for standards, because the range of naturally occurring D/H concentrations is so large that calibration with a single standard can lead to significant errors for samples of isotope ratio that are very different than the single standard. In 1978, Gonfiantini (1978) proposed a normalization of hydrogen and oxygen isotopic data by using δD and $\delta^{18}O = 0\text{‰}$ for the reference water *Vienna-Standard Mean Ocean Water* (V-SMOW), and $\delta D = -428\text{‰}$ and $\delta^{18}O = -55.5\text{‰}$ for the reference water *Standard Light Antarctic Precipitation* (SLAP), creating the VSMOW-SLAP scale. Individual instruments analyze VSMOW and SLAP, and assign the quoted values to the SLAP data, where the subscript represents normalization to the VSMOW-SLAP scale (Coplen, 1988; 1996). This calibration is known in the isotope ratio field as a "stretching or shrinking" of the isotope ratio scale, so that a second reference material is set to a defined δD value relative to the first reference material. In essence, this procedure is a two-point calibration of ion-current ratio to isotope ratio.

II. DUAL INLET ANALYSIS

A. Off-Line Sample Preparation for Organics

We briefly mention off-line sample preparation for dual inlet analysis. A more detailed discussion is available in previous *Mass Spectrometry Reviews* articles on IRMS (Hatchey et al., 1987; Wong & Klein, 1986). Typically, off-line preparation involves multiple steps on custom-designed vacuum lines equipped with high-vacuum and sample-compression pumps, concentrators using cryogenic or chemical traps, reactions in furnaces using catalysts or true reagents, and microdistillation steps. Contamination and isotopic fractionation are possible at any step,

and, in general, manual off-line methods are slow and tedious, usually requiring large sample amounts, and often requiring considerable operator skill and stamina to produce useful results.

A purified organic sample can be combusted to CO_2 and H_2O using cupric oxide (Wong & Klein, 1986), either by a static method (Sofer, 1980; Schimmelmann & DeNiro, 1993), where the sample is oxidized in an evacuated sealed tube (Boutton et al., 1983) containing copper oxide at $>700^\circ C$; or by a dynamic method (Craig, 1953), where combustion is performed in a vacuum line in the presence of excess oxygen. CO_2 can be analyzed directly or cryogenically separated from the water, and analyzed for its $^{13}C/^{12}C$ ratio using dual inlet analysis. For D/H measurement, the purified water can be reduced by zinc at $>450^\circ C$ in a sealed tube (Coleman et al., 1982) or dynamically reduced over hot uranium (Frazer, 1962) or zinc (Friedman, 1953) with subsequent dual inlet analysis. However, problems of isotopic fractionation and sample memory effects (Wong, Cabrera, & Klein, 1984) result from the difficulty with working with water vapor. The direct conversion of organic hydrogen to hydrogen gas utilizing pyrolysis at $>900^\circ C$ (Sofer, 1986; Sofer & Schiefelbein, 1986) can eliminate the need for handling water vapor in a vacuum line.

Nitrogen samples can be converted to ammonium by Kjeldahl digestion for total nitrogen analysis, followed by ammonium oxidation to nitrogen gas by the Rittenberg technique (Sprinson & Rittenberg, 1949) for $^{15}N/^{14}N$ isotopic analysis (San Pietro, 1957). A superior alternative to this technique is Dumas combustion (Steyermark, 1961), where organic matter is converted to nitrogen in a single-step process (Wada et al., 1977; Pella, 1973). However, the use of an apparatus that is usually employed for nitrogen isotope analysis can lead to inaccuracies through contaminants such as CO , small hydrocarbons, and nitrogen oxides, which produce isobaric interferences with the masses of interest (m/z 28, 29, 30). A combustion procedure using calcium oxide for total removal of CO_2 and H_2O has been developed and helps avoid these problems (Kendall & Grim, 1990). All of these off-line chemical techniques for C, H, and N isotopic analysis are very laborious and time-consuming. Usually, the determination of $^{18}O/^{16}O$ ratio in organic matter is performed by mass spectrometric analysis of CO_2 . Nickel is often used for organic combustion to CO_2 (Brenninkmeijer & Mook, 1981) or samples can be prepared using the $HgCl_2$ pyrolysis method at $550^\circ C$ described by Hayes (Schimmelmann & DeNiro, 1993; Wedeking & Hayes, 1983).

B. Water Analysis

The isotopic analysis of D/H and $^{18}O/^{16}O$ in water is a special application of particular interest to nutritional and

environmental studies. A useful review of off-line sample preparation for D/H and $^{18}\text{O}/^{16}\text{O}$ isotopic analysis of water and organic samples appeared in a previous *Mass Spectrometry Reviews* article (Wong & Klein, 1986). The inconvenience of the off-line static sample preparation for water analysis using the chemical reduction routine particularly for D/H measurements can be reduced by the use of batch processing (Kendall & Coplen, 1985) but off-line preparation continues to demand high operator skill and stamina to produce acceptable results. Electrolytic conversion of water to molecular O_2 and H_2 (Kirshenbaum, 1996) for subsequent isotopic analysis is problematic due to severe fractionation without complete conversion. The procedure is time-consuming and requires large sample quantities (Wong & Klein, 1986), but can be brought down to 20 min per sample with a microelectrolyzer (Bocek, Deml, & Tesarik, 1973).

Direct mass spectrometry of water has been attempted for O isotopic measurements with limited success. An on-line, static system commercially available in the 1980s allowed the simultaneous determination of D/H and $^{18}\text{O}/^{16}\text{O}$ in aqueous samples (Wong, Cabrera, & Klein, 1984). This system consisted of an on-line uranium furnace, for conversion of H_2O to hydrogen gas, preceding a dual mass spectrometer for HD/ H_2 and $\text{H}_2^{18}\text{O}/\text{H}_2^{16}\text{O}$ detection. This system suffered from severe memory effects and required a washout procedure consisting of more than six injections of a sample between analytes of different enrichment before accurate data could be obtained.

An alternative that requires very little operator interaction is the equilibration techniques that have been used for $^{18}\text{O}/^{16}\text{O}$ for decades, but only recently have been practically applied to D/H. The $^{18}\text{O}/^{16}\text{O}$ ratio is measured from CO_2 , with known O isotopic composition, equilibrated with the water sample at room temperature (Cohn & Urey, 1938):

The D/H ratio is measured from H_2 , with known H isotopic composition (Horita et al., 1989; Coplen, Wildman, & Chen, 1991), equilibrated with the water sample:

The use of these chemical equilibration methods for water analysis reduces sample preparation requirements compared to chemical reduction. The isotopic composition of hydrogen in equilibrium with water can be very temperature-dependent (6‰/°C). To achieve reproducible results using a fast equilibrating Pt catalyst, extremely high temperature stability is necessary (± 0.1 – 0.05°C). Slow equilibrating Pt reagents are the only viable solution yet demonstrated to mitigate the effects of this sensitivity (Scrim-

geour et al., 1993). In addition, these methods produce hydrogen gas with a severely depleted D/H ratio, which is taken into account during the calibration procedure. Because precision depends on the number of counts of the less abundant isotope, this depletion requires additional measurement time to yield precisions that are equivalent to samples that are less fractionated during their preparation.

SO_2 is the most common gas employed for S isotopic analysis; however, SF_6 has been used and has the advantage that F is monoisotopic so that there are no isobaric interferences with S isotopes. Off-line conversion of sample S to SO_2 requires several chemical steps in which the sample is first converted to BaSO_4 by acid digestion/precipitation followed by reduction to H_2S and a multistep conversion to SO_2 , as outlined elsewhere (Giesemann et al., 1994). These procedures typically require four hours per sample to generate isotopically representative SO_2 .

III. CONTINUOUS-FLOW (CF) IRMS

The seeds for CF-IRMS derive from the early days of organic MS, when it was shown that separation coupled to analysis by MS yielded results of unparalleled sensitivity, speed, and usefulness. Interfaces between gas chromatographs (GC) and MS, and later other separation devices and MS, focused on the continuous delivery of an analyte with intact structure to the MS in a gas phase form for structural analysis.

The earliest articles to demonstrate purposeful on-line chemical alteration prior to MS intending to simplify isotopic analysis appeared in the late 1970s, starting with Sano and coworkers (Sano et al., 1976), who coupled a GC to an organic MS by means of a combustion furnace. They combusted their sample to CO_2 and set the mass spectrometer to alternate between masses 44 and 45, thereby monitoring the carbon isotope ratio. Their samples were metabolites of a ^{13}C -labeled drug, from which they identified labeled peaks as indicative of metabolic activity. Soon afterward, Matthews and Hayes reported a GC-combustion-MS system based on a single collector organic MS (Matthews & Hayes, 1978). The GC effluent was combusted, and dried with a semipermeable membrane, NafionTM, which passes water and retains CO_2 . The dried effluent was admitted to a single collector MS that was optimized for isotopic analysis and that determined C and N isotope ratios. The system was the first to yield sufficient precision to detect isotope ratio variability in natural sources in compounds separated on-line. Four years later, Markey and Abramson reported a similar approach with on-line chemistry called the chemical reaction interface (CRI) MS, which is based on the processing of a GC effluent in a microwave cavity to yield small molecules for isotopic analysis at low precision for biotracer experiments

(Markey & Abramson, 1982). All of these systems rely on a carrier gas to transport the analyte through a stage of on-line chemistry for conversion to a form acceptable by the MS. This process is one of the fundamental principles underlying CF-IRMS.

A. Bulk Samples: Elemental Analyzer

With the wide use of stable isotopes for bulk analysis in fields such as geochemistry, ecology, biomedicine, and nutrition, a great demand exists for the rapid analysis of large numbers of solid samples. Time-consuming conventional preparation techniques are difficult to automate, and they limit the number of samples that can be analyzed.

A classical method for elemental analysis is based on the flash combustion of samples in a furnace followed by quantitative analysis of the resulting gases (Holt & Hughes, 1955). A commercially available approach to these analyses is automated flash combustion followed by GC separation of CO_2 and N_2 and nondestructive detection using a thermal conductivity detector, with the effluent stream ultimately vented to waste.

In 1983, Preston and Owens (Preston & Owens, 1983) demonstrated the first CF interface to a multi-(dual) collector IRMS for the bulk analysis of nitrogen from solid samples. Precisions of about $\text{SD}(\delta^{15}\text{N}) = 0.7\text{‰}$ were obtained for $3.5 \mu\text{mol}$ aliquots of N_2 derived from urea in the CF mode after flash combustion and separation in a GC equipped with a gas separation column. These authors observed a degradation in the precision due to ion source nonlinearities when analyzing samples of varying size, as is now observed in demanding CF analyses. This system was the first high-precision multicollector CF-IRMS. Two years later, these authors extended the instrument to the analysis of C with similar reproducibility (Preston & Owens, 1985).

Modern commercially available elemental analyzers provide an automated means for on-line high-precision isotope ratios for bulk analysis of solid and nonvolatile liquid samples. Samples are placed in a capsule, typically silver or tin, and loaded into a carousel for automated analysis. The sample is dropped into a heated reactor that contains an oxidant, such as copper oxide for C or S analysis, where combustion takes place in an He atmosphere with an excess of oxygen. Combustion products are transported by flowing He through a reduction furnace for removal of excess oxygen and conversion of nitrous oxides into N_2 . A drying tube is used to remove any excess water in the system. The gas-phase products are separated by GC, and detected nondestructively by thermal conductivity before introduction to the IRMS. Recent work has demonstrated the analysis of S isotopes (Giesemann et al., 1994), where samples must first be converted to BaSO_4 prior to loading into the elemental analyzer. For all elements, ini-

FIGURE 2. Diagram of the *Cryoflow* system for cryofocusing of analyte gases derived from an elemental analyzer (redrawn from [Fry et al., 1996]). Furnace temperature, He carrier flows, and trap conditions are adjusted for optimal analysis of CO_2 , N_2 , or SO_2 . For instance, for CO_2 analysis the furnace is held at 600°C with a slow He flow rate of 2 mL/min , trap 1 is at -86°C to remove water, and trap 2 is either immersed in liquid nitrogen to concentrate CO_2 or $+22^\circ\text{C}$ to release CO_2 . Trap 3 is necessary for SO_2 only.

tial sample sizes in the mg range are most easily analyzed with these instruments.

Oxygen and hydrogen are the two most recent elements for which elemental analyzer data for bulk compounds have been presented. Oxygen-containing samples are converted on-line to CO by pyrolytic reaction with carbon (the "Unterzaucher reaction") as first shown by Brand et al. (Brand, Tegtmeier, & Hikert, 1994), using a GC-based system; several other reports using this principle subsequently appeared, showing elemental analyzer (Koziet, 1997; Werner et al., 1996) or direct injection analysis (Begley & Scrimgeour, 1997). The very recent report of Farquhar et al. (Farquhar, Henry, & Styles, 1997) demonstrates the automated on-line conversion of the oxygen in water or nitrogen-containing plant dry matter to CO, using a pyrolysis-based reaction on nickelized carbon at about 1100°C . CO is separated from N_2 , using a GC with a molecular sieve column; precisions of $\text{SD}(\delta^{18}\text{O}) = 0.2\text{‰}$ are obtained. Begley and Scrimgeour (1997) have shown the analysis of oxygen and hydrogen (δD) on a single sample by measuring the isotope ratio of H_2 gas produced in the pyrolytic reactor with a high mass dispersion IRMS, with an abundance sensitivity that capable of fully resolving analyte HD from excess ^4He carrier. Precisions for water, urine, and volatile organic compounds are about $\text{SD}(\delta\text{D}) = 2\text{‰}$ and $\text{SD}(\delta^{18}\text{O}) = 0.3\text{‰}$.

Low sample size analysis has been an important goal in recent instrument work. Fry et al. (Fry et al., 1996) described an elemental analyzer-IRMS system for measuring C, N, and S isotopic compositions of gas samples in the 10–1000 nmol range. In this CF interface shown in Fig. 2, which the authors refer to as *Cryoflow*, samples are injected or dropped into a quartz tube that is partially filled with reduced copper and that is held at a temperature

of 600–1000°C, with a continuous flow of He. For samples requiring combustion, oxygen was added directly from a tank, or by mixing the sample with V₂O₅, or a combination of both. After reaction in the combustion furnace, gases are transported by normal high flow-rates of He through a series of traps for purification and collection of the target analyte. Once the analyte gas is trapped, the flow-rates are lowered and the trap is heated to permit flow of the analyte into the IRMS. In this interface, all separation is conducted via cryogenic traps; no column is used, as is the case with the standard elemental analyzer interface. In this sense, the system is a hybrid between a CF and batch system, but clearly demonstrates that the CF principle works well with cryotrapped analyte. Sequential analysis of all three elements is possible for a single sample by holding analyte gases in the traps while the IRMS tuning is adjusted to optimize for each element. Straightforward modifications to the IRMS should make possible the automated analysis for all three elements. Precisions of $SD(\delta) < 0.3\text{‰}$ for samples > 50 nmol C, N, or S could be routinely obtained.

B. Trace Gases

Interest in stable isotope measurements of trace gas species, particularly CH₄, N₂O, and CO₂, continues to increase because of the utility of isotopic information for interpreting concerns such as climate change, global warming, O₃ production, and OH depletion (Conny & Currie, 1996; Morse et al., 1996; Ciais et al., 1995). CH₄ carbon isotope ratios in natural systems are indicative of mechanisms and pathways of CH₄ cycling (Sansone, Popp, & Rust, 1997). It is frequently desirable to determine high-precision isotope ratios of environmental gases present at very low ambient concentrations in either gas or dissolved form. An example is atmospheric methane analysis, which often requires 50 L of sample to yield sufficient methane for a precise isotopic analysis (Lowe et al., 1991). Considerable effort has been directed to optimize the detection limits for analysis of environmental trace gases, in the atmosphere, and dissolved in water. To address this problem, an automated cryogenic system, referred to as “PreCon,” was presented recently for analysis of N₂O and CH₄ (Brand, 1995). A 100 mL bulb of sample gas is mounted atop a unit equipped with one manual and two automated liquid N₂ traps that serve to concentrate or purify one of the two gases prior to a final purification by GC, before introduction to the IRMS. CH₄ originally at 1700 ppb in laboratory air was analyzed at a precision of $SD(\delta^{13}\text{C}) < 0.2\text{‰}$, whereas N₂O analysis produced about 0.2‰ for nitrogen and oxygen ratios.

In a very recent report, Sansone and coworkers demonstrate the operation of cryogenic trapping systems that are capable of the automated analysis of 200 pmol CH₄ dissolved in either water (1–50 nmol CH₄) or gas samples

[45–250 ppm CH₄ (v/v)] (Sansone, Popp, & Rust, 1997), as shown in Fig. 3. Water samples are automatically loaded into a sparging column, where dissolved CH₄ is removed by flowing He. Sequential drying and ascarite traps remove water and CO₂, respectively, before the CH₄ is cryotrapped prior to cryofocusing for GC-combustion-IRMS analysis (to be discussed below). Precisions were $SD(\delta^{13}\text{C}) = 0.8\text{‰}$ for replicates of 1.5 or 25 nM CH₄ in seawaters. These authors also describe preparation systems for low-level gas analysis, where trace quantities of CH₄ are purified, preconcentrated, and separated from O₂/N₂ prior to cryofocusing on a GCC-IRMS. Precisions of $SD(\delta^{13}\text{C}) = 0.3\text{‰}$ for a laboratory gas standard of about 100 ppm CH₄ in He are obtained.

C. Breath Tests

The isotopic analysis of breath CO₂ is increasingly important in biomedical applications because of numerous putative diagnostic tests that rely on the measurement of isotopic labeling of breath CO₂ after oral ingestion or injection of a test substance (Halliday & Rennie, 1982). Typically, a substrate is chosen so that the labeled substance is metabolized to CO₂ at a rate that is limited by the process to be measured. The labeled CO₂ is diluted many-fold by a much larger volume of body CO₂ before being expired, leading to very small enrichments over baseline and the attendant requirement for high-precision analysis. The ¹³C breath test is a nonradioactive alternative to ¹⁴C breath tests, and has been validated for use in clinical diagnosis and medical research for the detection of a number of conditions, including pancreatic functional impairment (Watkins et al., 1977), gastric emptying (Ghoos, Rutgeerts, & van Trappen, 1985), and gastric infection by *Helicobacter pylori* (Marshall & Verdun, 1990).

CO₂ must be purified from an excess of water vapor and air gases prior to analysis. Automated systems based on cryogenic purification have been used for years (Schoeller & Klein, 1979), but are slow and cannot be used for samples from subjects whose breath is contaminated with appreciable concentrations of gases that co-condense with CO₂ or that yield isobaric interferences, such as ethanol or ketones. CF analysis of breath was first conducted by manual injection of sample into the carrier flow of an elemental analyzer interfaced to an IRMS (Preston & McMillan, 1988). This system avoided cryogenic purification by using a GC column to purify CO₂. A fully automated system was described soon afterward that samples breath gas from vacutainers along with GC purification (Prosser et al., 1991). Commercial dedicated systems are now available for breath gas analysis from four manufacturers based on very similar principles.

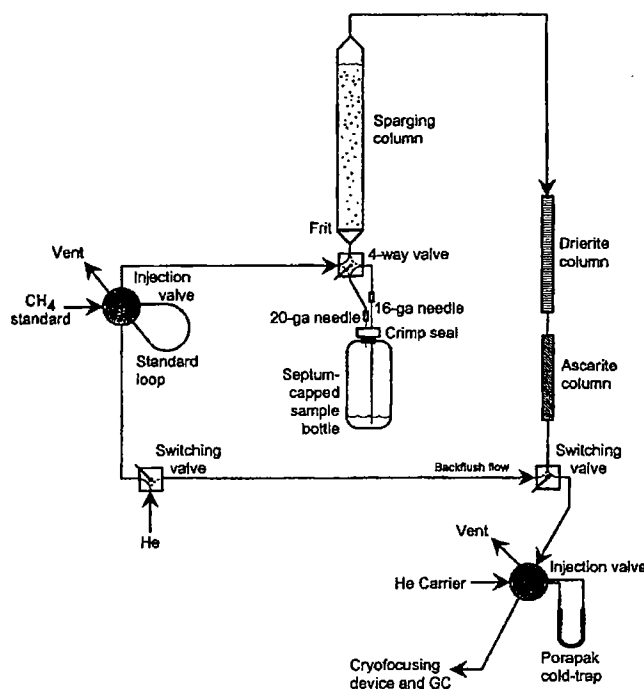

FIGURE 3. Diagram of the automated sparging system from Sansone et al. (Sansone, Popp, & Fry, 1997). Sample water is loaded into a sparging chamber and dissolved gases are removed, purified through drying and ascarite traps, and cryogenically concentrated for analysis. The IRMS (not shown) is located after the GC (reprinted with permission from *Anal. Chem.* 1997, 69, 40–44, Fig. 1, copyright American Chemical Society, 1997).

IV. COMPOUND-SPECIFIC ISOTOPE ANALYSIS (CSIA)

A. Gas Chromatography (GC) and Carbon

The first high-precision GC-combustion-IRMS (GCC-IRMS) based on a multicollector IRMS drew from the early work on GC-combustion (Matthews & Hayes, 1978) to demonstrate that isotopic analysis with a dual collector instrument produced isotope ratios an order of magnitude more precise than demonstrated for an optimized single collector instrument. Barrie et al. (Barrie, Bricout, & Koziat, 1984) used a combustion furnace filled with Co_3O_4 coupled to a cryogenic water trap to prepare CO_2 from a mixture of natural flavoring compounds. Precisions were about $\text{SD}(\delta^{13}\text{C}) = 1\text{‰}$, with a small negative bias of about 1‰ observed for the calibration with CO_2 gas; that bias was nearly eliminated when calibration was conducted against an analyte peak used as an internal standard.

Many acronyms are in use to describe essentially the same fundamental instrument approach. GC-IRMS and GC-C-MS were used for the earliest commercial instruments by separate manufacturers. The term “mass fragmentography” used by Sano and coworkers was replaced by the earliest acronym to be widely adopted, “isotope

ratio monitoring GC/MS” (irmGC/MS) introduced by Matthews and Hayes (1978). The latest may be Compound-Specific Isotope Analysis (CSIA), introduced recently by Schoell (Brand, Tegtmeier, & Hilkert, 1994; Schoell & Hayes, 1994). None of these abbreviations includes the distinguishing characteristic of the technique as now practiced, high-precision, and most could be used to describe other analytical techniques. Because the choice is rather arbitrary and they are not linked to commercial instruments, we use *GCC-IRMS* or *LCC-IRMS*, and high-precision *CSIA* (or *PSIA* below) when a more general term is desirable.

Fundamentals of the modern GCC-IRMS instrument for the analysis of carbon isotopes differ very little from the principles in Matthews and Hayes (1978) and in Barrie et al. (Barrie, Bricout, & Koziat, 1984). Commercial instruments have been available since 1990 with metal oxide combustion furnaces and either Nafion or cryogenic water traps. A schematic of an instrument is shown in Fig. 4 (Goodman, 1997). The GC is an standard capillary system with any of the usual injectors, split/splitless or on-column. The GC effluent is directed to a combustion reactor, which is normally a ceramic or quartz tube with capillary connections at the entrance and exit. The reactor is usually loaded with a metal oxide derived from oxidizing metal wire,

FIGURE 4. Diagram of a GCC-IRMS instrument, after Goodman (1998). A conventional GC is interfaced to a switchable valve that directs the column flow to waste while the solvent peaks elute, or to the combustion furnace when analyte elutes. In the waste mode, He with a small concentration of O_2 for reagent recharge flows through the furnace. The combustion reactor converts organics to CO_2 and H_2O , using CuO reagent and Pt as a catalyst. The capillary is bathed in cryogen to trap water, then is directed to an open split for admission of purified CO_2 to the IRMS.

such as Cu, along with Pt catalyst intended to promote completion of the oxidation reaction. At $600^\circ C$, CuO is a source of O_2 via

As is clear from this equation, CuO is a secondary reagent in the reaction and must be replenished periodically. This replenishing (or "recharging") can be accomplished automatically by including a small amount of O_2 in the stream of carrier gas flowing through the furnace in-between samples (Merritt et al., 1995). It is necessary to divert solvent peaks away from the furnace, because solvent would otherwise prematurely deplete this reagent. Most systems accomplish this diversion by a backflush switching of flow pressure under computer control so that He is forced back through the furnace toward the capillary column (Goodman & Brenna, 1992). Because optimal flow-balancing can be time-consuming, an automated rotary valve can be substituted in place of the backflush. The valve switches solvent flow to waste (or a flame ionization detector) while clean He is flowing through the furnace, or connects the capillary with the furnace once the solvent peak has eluted, as shown in the Fig. 4.

CO_2 and H_2O representative of the combusted organic analyte emerge from the furnace. Water must be removed prior to admission to the ion source because it protonates CO_2 to produce HCO_2^+ , which interferes with analysis at m/z 45. Either a NafionTM tube or a cryogenic trap is employed to remove the water of combustion. A Nafion-type trap consists of a length of the fluorinated polymer tube attached to a capillary at its entrance and exit. The analyte stream passes into the tube, where water passes through

the walls and is swept away with counterflowing He, while CO_2 is quantitatively retained. This trap offers the advantage that it operates continuously at room temperature without attention. Its principle disadvantage is that it introduces two connections, which offer the possibility of leaks, as well as two diameter changes, which compromise chromatographic resolution.

The cryogenic trap shown in Fig. 3 consists simply of a length of capillary or tubing bathed in an appropriate cryogen, which retains water but passes CO_2 . This approach has the disadvantage that the trap must be warmed periodically to remove trapped water. However, as shown in Fig. 3, it offers the possibility of using a continuous capillary from the end of the GC column through the combustion furnace and water trap and directly to the open split leading to the IRMS. In this design, the oxidant wire is threaded into the capillary to an appropriate point, and the capillary is anchored at each end of a ceramic tube. One end of the capillary is attached to the rotary valve in the instrument, and the end emerging from the furnace passes through a cryogen bath and to the open split. When the furnace is first operated, the protective polyimide coating outside the capillary burns away to leave a bare fused silica capillary that is mechanically stabilized at the furnace temperature by the ceramic tube. This system is resilient in use over many months as long as the furnace temperature is maintained, and offers the advantage of best-case chromatography and leak-free operation as long as capillary continuity is maintained. The open split referred to above is required to feed analyte gas at a stable flow rate to the IRMS; splits of this sort are common in MS applications.

High column bleed is a particular problem in GCC-IRMS, because the combustion furnace converts all organic compounds to CO_2 before analysis. Unlike the organic MS, no additional separation based on mass analysis is possible. Hence, high bleed rates translate into high backgrounds and diminished dynamic range.

Carbon isotope data from a single GC peak are shown in Fig. 5. Three traces, representing masses 44, 45, and 46, are recorded as the analyte CO_2 passes through the ion source. The peaks are intentionally of comparable magnitude because of the mismatch of amplifier gains that was mentioned previously. For CO_2 , the relative gains in the Finnigan MAT 252 are 3 to 300 to 1000 for m/z 44, 45, and 46 channels, respectively. The ratio of m/z 45 to 44 is plotted above the chromatograph to illustrate the commonly observed phenomenon that the 45 peak is observed to elute prior to the 44 peak, yielding a "positive-negative going" ratio trace. This reversal is thought to be due to the differences in intermolecular interactions between the isotopically substituted peaks and all ^{12}C peaks. These traces are used to generate integrated areas by applying either the summation or curve-fitting algo-

FIGURE 5. Traces of the m/z 44, 45, and 46 mass channels as a GC peak are analyzed in the IRMS. The signals are of comparable size, because the amplifications are set to match natural abundance. Peaks are integrated and areas are used to calculate isotope ratios.

gorithms, as discussed above. Isotopic calibration can be accomplished if one of the peaks in the chromatograms is an internal standard (Caimi, Houghton, & Brenna, 1994). More commonly and conveniently, a pulse of calibrated CO_2 from a gas bottle is admitted to the ion source through a separate inlet during a period where no peaks elute from the GC. Precisions of $\text{SD}(\delta^{13}\text{C}) < 0.3\text{‰}$ are routine for well-resolved, strong peaks that are integrated and calibrated in this way. For carbon, the minimum sample size required to yield a precision of this level is about one nmole carbon (Merritt et al., 1995; Goodman & Brenna, 1992; Merritt & Hayes, 1994).

One of the analytical limitations of GC-combustion is the dynamic range over which enrichments can be accurately and precisely measured. In our hands, carbon isotope ratios much above $\delta^{13}\text{C} = 1000\text{‰}$ will compromise precision and accuracy, partly due to the large difference in isotope ratio between them and natural abundance standards. This problem can be remedied in part by the use of enriched standards; however, this measure does not overcome the mismatch in amplifications among the channels, which, as noted previously, are set to make natural abundance signals of nearly equal magnitude. It is very difficult to overcome this problem, because the amplifiers must be set simultaneously to the ratio anticipated for the enriched samples and for the baseline samples, which inevitably are analyzed in the same chromatogram.

An alternative solution to this problem has been pre-

sented, where the GC is simultaneously coupled to a combustion-IRMS system and an ion trap mass spectrometer (Meier-Augenstein et al., 1994; 1995; Meier-Augenstein, 1995). The flow of separated analytes emerging from the capillary column is sent through a splitter, which sends about 10–20 parts to the combustion-IRMS and one part to the ion trap. The split ratio is chosen in these proportions, because the ion trap can detect with ease sub-nmoles of most organic compounds, whereas the IRMS requires higher analyte levels to maximize counting statistics. Excellent linearity was achieved throughout the low and high enrichment ranges, indicating that this approach is the means of choice for wide dynamic range determination of carbon isotope ratios.

B. CSIA/CF Data Analysis

A separate discussion of data analysis for CF data is warranted and is best considered for GCC-IRMS of carbon, for which most of the work has been done and is suitably representative of all but hydrogen analysis. One of the commercial data analysis algorithms in routine use has been published in some detail (Ricci et al., 1994), and is based on the most common algorithm used for chromatographic peak analysis, known as the “summation” method. The start of a peak is identified in the highest abundance mass channel trace (m/z 44 for CO_2) by comparing the slope from a rolling five-point regression to a user-defined threshold, and the end of a peak is determined as the first point after the apex that drops below some fixed percentage of the apex maximum. The most abundant peak is used, because it will have the highest signal-to-noise (S/N) ratio. Peaktops are defined in the other mass channels. Because of the slightly differing chromatographic elution times of isotopomers, the mass scales of the other channels are adjusted so that apices of all mass channels correspond in a procedure known as “time-shifting,” in order to identify the peak starts and stops. The background can be identified and subtracted, and the excess peak area summed to yield the abundances. These peak areas are ready for calibration. This procedure works well near natural abundance, but is less effective at very high enrichments, where the area of the minor isotope peak, for instance m/z 45, is of disproportionate size and is not subsumed by the major isotope. Tails of the m/z 45 peak extend well beyond the limits of the m/z 44 peak, and are not integrated. The solution to this problem is to use the m/z 45 peak for detection and to time-shift the m/z 44 channel. This process, in our experience, compromises little in terms of effective peak detection but significantly improves the results.

There are a few published studies on various issues and data processing. We investigated the effects of incomplete chromatographic resolution on the calculation of iso-

FIGURE 6. (a) Results of a study of the effect of peak overlap on isotope ratios calculated from areas derived by the summation method (open symbols) or by curve-fitting (closed symbols) (Goodman & Brenna, 1994a). Two compounds (methyl tridecanoate and butylated hydroxytoluene) of nearly equal $\delta^{13}\text{C}$ are analyzed individually and under chromatographic conditions producing graded overlap. Isotope ratios determined by summation start to diverge from best values at 10% valley even though precision is unaffected. Curve-fitting using the exponentially modified gaussian function retains precision and improves accuracy. (Reprinted with permission from *Anal. Chem.* 1994, 66, 1294–1301, Fig. 5, top left panel, copyright American Chemical Society, 1994.) (b) Results of a study of curve-fitting on well-resolved, low signal-to-noise peaks (Goodman & Brenna, 1994b). Curve-fitting (open symbols) produces considerably better accuracy and precision than conventional summation (closed symbols). (Reprinted from the *Journal of Chromatography*, Vol. A 689, Fig. 3, pp. 63–68, 1995, with kind permission of Elsevier Science–NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.)

tope ratios by the summation method and by curve-fitting, using several functions designed for chromatographic applications (Goodman & Brenna, 1994a). This procedure consists of nonlinear least-squares fitting, using the Marquardt–Levenberg algorithm to interrogate parameter space. Goodness-of-fit parameters are calculated for each set of fitted coefficients and the best values are determined by iteration. The final, fitted-area parameter is used in

further ratio calculations. Figure 6(a) shows the results of increasing peak overlap on calculated isotope ratios for two compounds, methyl tridecanoate (Me13:0) and butylated hydroxytoluene (BHT) that were separated using a capillary column, combusted on-line, and admitted to the IRMS. The two compounds had carbon isotope ratios that matched to about 0.5‰ of one another. For an equal abundance mixture and at an overlap as small as 10% valley, the isotope ratios are significantly different, with the earlier-eluting compound apparently depleted and the latter-eluting apparently enriched by about 1–2‰. At 70% overlap, the isotope ratios have diverged so that they are 7–10‰ from the correct value. The remarkable observation is that the precisions are excellent for all but the 70% valley case, indicating that even small amounts of overlap have a dramatic effect on isotope ratios calculated from areas using the summation method. The degradation in accuracy is *not* apparent from any degradation in the precisions. The effect is even more pronounced for the smaller of a pair of mismatched peaks. Figure 6(a) also shows that curve-fitting with a common chromatographic function, the exponentially modified gaussian, recovers the accurate isotope ratio without sacrificing precision, up to a 40% overlap.

Further work on curve-fitting (Goodman & Brenna, 1994b) showed that precision could be preserved at very low signal levels with curve-fitting for well-resolved peaks, as illustrated in Fig. 6(b). Curve-fitting's strength is well-known to be superior for low S/N data, and our results confirmed this observation for CF isotope ratio analysis—as shown. Thus far, curve-fitting has not been incorporated into any commercial IRMS data reduction software.

Others have shown that the time-shift procedure is critical to preserve accuracy when chromatographic parameters are altered (Meier–Augenstein, Watt, & Langhans, 1996). For example, the alteration of temperature-ramping parameters, which produce an alteration in background slope due to column bleed, caused changes in calculated isotope ratios. The most straightforward method to deal with this problem is to employ an isotopically calibrated standard that elutes at precisely the same time as the analyte. However, this procedure is much less convenient than the simple inclusion of a pulse of isotopically calibrated gas at an uncluttered section of the chromatogram.

C. GC and Nitrogen

In 1994, descriptions of two systems were published that demonstrated the high-precision CSIA of N (Preston & Slater, 1994; Merritt & Hayes, 1994) on multi-collector instruments, and that applied to amino acid analysis. The two most important challenges to N analysis are the very

low concentration of N in organic compounds compared to C, and the necessity to prepare N_2 , which requires reduction chemistry, as opposed to C, which requires oxidation. The system of Preston and Slater directs the output of the analytical GC to a conventional combustion furnace, which converts volatile amino acid derivatives into CO_2 , CO , H_2O , and N_2 with, presumably, nitrogen oxides as well. A cryogenic trap removes water, CO_2 , and higher oxides of N, and a second GC separates N_2 from CO . That overlap would be a serious isobaric interference at m/z 28 if CO were permitted to enter the IRMS. For seven nmol of phenylalanine, these authors report a precision of $SD(\delta^{15}N) = 5\%$ by using an internal standard, and they report that this precision is limited by the precision of their IRMS.

Merritt and Hayes reported a similar system with the addition of a reduction reactor loaded with Cu wire to reduce N-oxides to N_2 and to remove O_2 , and with the use of a higher precision IRMS. Their system also included a combustion furnace and cryogenic trap for water removal, and it produced a precision of $SD(\delta^{15}N) = 0.2\%$ for a sample size of two nmol of an amino acid, with an accuracy better than 0.05% . This system's performance was superior at the expense of added complexity.

D. General CF Analysis of Hydrogen

The methodology for CF analysis of C and N isotopes involves advanced on-line sample chemistry with microreactors and separation traps, and can be applied to aspects of hydrogen isotopic analysis. However, obstacles to CF-IRMS of hydrogen isotopes, such as memory effects due to water, make H a more formidable goal. For instance, experience with a dual IRMS that was introduced in the mid-1980s and designed to analyze water samples directly injected into an inlet suffered severe memory effects and required 6–20 injections between sample changes to flush the system of any remaining previous sample (Wong, Cabrera, & Klein, 1984). This system did not use an He carrier, and, therefore, was not a CF system in the modern sense.

In CF methodology, the inert carrier gas, usually pure He, is used to sweep the analytes of interest into the mass spectrometer. He presents another challenge for IRMS H analysis because it interferes with an HD measurement in two ways. First, standard laboratory grade He gas contains ~ 1 ppm 3He isotope that adds to HD measurement, but can be corrected for by background subtraction. Second and much more important, the abundance sensitivity of conventional IRMS is not great enough to resolve HD from the tail of a much greater $^4He^+$ beam. The $^4He^+$ tail often results in a saturated m/z 3 detector. Other obvious inert gas choices that might be used as a carrier, such as Ne, Ar, and Xe, have numerous disadvantages including

FIGURE 7. Effect of coadmitted N_2 on hydrogen isotope ratios. The presence of N_2 co-admitted to the ion source with H_2 (▲) measurably alters the ion current ratios determined for HD/H_2 , compared to pure H_2 (●), in part because of isotope-dependent reactions in the ion source. Hydrogen, including contaminants from, for instance, combustion/reduction of N-containing compounds, will be subject to this bias and may not be effectively calibrated using pure gas.

(1) compromised chromatographic resolution due to their high mass, (2) very high densities and low ionization potentials compared to He, leading to high-intensity ion beams that rapidly damage ion optical components and insulators that lead to electronic problems (Tobias et al., 1995), (3) for Ne and Xe, very high cost, and (4) sensitivity of isotope ratio to co-admitted contaminants. The latter effect is demonstrated in Fig. 7, where a co-admitted contaminant, N_2 , produces a statistically different D/H than for pure H_2 . This difference can be an important consideration in organic analysis using chromatography, where heteroatoms such as N or S will be converted to stable species that will be admitted to the ion source along with the analyte gas unless a purification step is included.

In 1995, Prosser and Scrimgeour (Prosser & Scrimgeour, 1995) introduced a novel mass spectrometer with an extra collector spur, using a large radius that achieves a high dispersion of m/z 3 from m/z 4. The diagram in Fig. 8 shows the simultaneous detection of the m/z 2 and 3 beams, whereas the m/z 4 beam (not shown) is not sufficiently deflected in the magnetic field and collides with the flight tube walls. This configuration yields remarkably high abundance sensitivity, and prevents any measurable interference from 4He without resorting to elaborate high-vacuum pumping systems common in high abundance sensitivity TIMS instruments.

Another approach developed at the same time by Tobias et al. (1995) is the Pd filter system (PFS), in which carrier is completely prevented from entering the IRMS ion source. A Pd foil membrane held at elevated temperatures is used to selectively admit only hydrogen and deuterium into the MS while diverting the carrier gas to waste.

FIGURE 8. Diagram of a high-abundance sensitivity IRMS tailored to the CF analysis of hydrogen in He carrier gas (Prosser & Scrimgeour, 1995). The tail of the very large ^4He normally interferes with HD at m/z 3 is eliminated using very high dispersion. H_2 at m/z 2 and HD are detected simultaneously while ^4He at m/z 4 collides with the vacuum chamber walls. (Reprinted with permission from *Anal. Chem.* 1995, 67, 1992–1997, Fig. 1, copyright American Chemical Society, 1995.)

This membrane can be made of pure Pd metal, but more often is a Pd alloy. A vanadium alloy, with a thin plate of Pd on both surfaces, can also be used to facilitate greater permeability and lower dependence of isotope permeability on temperature (Tobias & Brenna, 1996). These two developments facilitate the CF-IRMS of H isotopes and permit the development of on-line chemical techniques for specific sample analyses.

E. Water Analysis

Prosser and Scrimgeour demonstrated a CF-IRMS method for water analysis with their high dispersion instrument. They applied the method of Horita (Horita et al., 1989), wherein water and hydrogen gas are equilibrated with a Pt catalyst (Prosser & Scrimgeour, 1995), and report precisions of $\text{SD}(\delta\text{D}) < 4\text{‰}$ for the resulting hydrogen. Very recent, Begley and Scrimgeour reported a pyrolysis system for CF analysis of either water or volatile organics (Begley & Scrimgeour, 1997). Their system used carbon-coated nickel to convert water or volatile organics to H_2 and CO for the analysis of D/H or $^{18}\text{O}/^{16}\text{O}$, respectively. The IRMS was a high-dispersion instrument with sufficient abundance sensitivity to fully separate the tail of ^4He from HD. This system produces $\text{SD}(\delta\text{D}) = 2\text{‰}$ and $\text{SD}(\delta^{18}\text{O}) < 0.3\text{‰}$ for water or organic samples. A nickel plug inserted in the injection port prevents salts and nonvolatile organic matter from entering the system, and permits the direct

analysis of urine with a precision equivalent to that observed for water. Some memory effects of $<2\text{‰}$ are observed for both isotopes. This type of system has an inherent potential advantage over a PFS, because more than one isotope can be analyzed in a single analysis.

The direct analysis of pure hydrogen gas, using the PFS with a pure Pd membrane, results in a precision of $\text{SD}(\delta\text{D}) < 6\text{‰}$. These data result from sample sizes that were matched to avoid nonlinearities associated with hydrogen isotopic analysis—that topic will be addressed in detail below. An on-line chemical reduction scheme developed by Tobias et al. can be used for direct water analysis for its D/H after conversion to H_2 (Tobias et al., 1995). Water samples (100 nL) are introduced into an He carrier stream via a GC injector, and are subsequently reduced to hydrogen gas by the use of a micro-reactor that is filled with Ni metal and is held at $>850^\circ\text{C}$. The use of a Nafion water trap eliminates problems associated with any residual unreduced water vapor, and it does not affect isotopic measurement. There is no evidence of memory effects over a $\delta\text{D} = 5000\text{‰}$ range in isotope ratio. This on-line chemical configuration is compatible with the high-dispersion instrument (Begley & Scrimgeour, 1996) and makes it convenient for doubly labeled water samples, because it can be used to analyze the isotopes of O and H from water by using the same instrumental configuration. Nickelized carbon can be used to generate CO from H_2O to allow for the analysis of $^{18}\text{O}/^{16}\text{O}$ from CO.

F. CF Analysis of Hydrogen: Correction Procedures

One of the critical issues facing CF H analysis is the presence of two nonlinear effects that result in ion current ratios that depend on the chemical composition in the ion source. One of these factors is the pressure-dependence mentioned previously and common to all IRMS elements. That dependence is effectively eliminated by the carrier gas background pressure. In chromatography experiments, CF analyte levels are difficult to match between different analyte components in a sample mixture and usually vary over a large range. This variation is an important consideration for hydrogen analysis as a result of the false contributions to the m/z 3 signal due to effects in the tight IRMS ion source that change with varying analyte quantity. The situation contrasts with dual inlet analysis, where sample and standard pressures are always equalized and such problems are easily addressed. Ion current ratios depend on the total gas pressure in the ion source due to pressure-dependent mass selection (Kirshenbaum, 1951). The selectivity toward the higher mass ions is observed because of the interaction of the fields from the collimating magnets on the acceleration of ions. In effect, the ion source acts like a small mass spectrometer. Space charge, which increases with the amount of analyte gas in the ion source chamber, also contributes to mass discrimination (Scrimgeour et al., 1993). For hydrogen, the second and much greater effect is the production of H_3^+ in an ion-molecule reaction that depends on hydrogen-hydrogen collision frequencies:

The H_3^+ formed in this reaction is proportional to the square of the amount of H_2 in the ion source, and is not resolved from HD in commercial IRMS instruments.

Empirical correction procedures for these effects have been proposed for over a 2-fold signal intensity range by Prosser and Scrimgeour (1995), and up to a 22-fold range by Tobias et al. (Tobias & Brenna, 1996). These effects depend on specific instrument tuning parameters. Any nonlinearities that result from, for example, unmatched m/z 2 and 3 detector time constants, can complicate correction procedures by introducing another second-order dependence of measured m/z 3/2 ion current ratios on m/z 2 peak area. Matching of detector responses results in a linear dependence and makes correction procedures more straightforward. In these procedures, the characterization and correction of ion source effects are conducted after hydrogen peak detection and isotope ratio calculation. Such procedures are referred to as *peakwise* to reflect their application after peak detection. These routines require the analysis of analyte over a wide signal range to characterize

FIGURE 9. Diagram of the Pd filter system (PFS) for CSIA of H using a GC. The GC effluent is sequentially combusted and reduced, and the flow is stepped up using a modified GC injector, and directed onto a Pd-V-Pd sandwich foil held at 600°C. Hydrogen and its isotopes diffuse through the foil at an efficiency of about 20%, while the carrier stream and any contaminants are vented to waste. (Reprinted with permission copyright American Chemical Society, 1996.)

and correct the nonlinearities. A *pointwise* correction, where characterization and correction of ion source effects are conducted before hydrogen peak detection and isotope ratio calculation, should not require correction data over a wide signal range. In our hands, a pointwise procedure was not effective, seemingly due to unknown effects from continuously varying signals (Tobias, 1997). Peakwise correction procedures prior to isotopic calibration are in current use for CF H analyses (Begley & Scrimgeour, 1997).

G. CSIA for Hydrogen

Tobias and Brenna (1996) first demonstrated CSIA for H using the PFS coupled to GC, with an apparatus shown in Fig. 9. An on-line combustion microreactor, filled with CuO held at 850°C, and a reduction reactor filled with Ni metal held at 950°C, are used to convert separated organics to hydrogen gas. Evaluation of the system, using benzene as an internal standard in a mixture of ethyl benzene and cyclohexanone in hexane, results in precisions of $SD(\delta D) < 5\%$ with organic analytes at quantities of < 3 ng (< 300 pg H). Similar results are demonstrated in a procedure developed for hydrogen isotopic analysis of components in natural gas mixtures using the PFS.

Long capillary columns are often required when analyzing complex mixtures of organics. We found that long capillaries lead to lower flow-rates and carrier pressures at the Pd filter, resulting in a decreased hydrogen sensitivity. A make-up pressure unit was inserted between the on-line reactors and the Pd filter to increase the pressure with which the carrier and analyte impinge upon the Pd surface to facilitate an increase in hydrogen transfer.

There are at least two serious problems with the on-line chemical conversion of organics to hydrogen. First, chemical reductants used to date have very limited lifetimes; in our hands, 8 h or so. This limitation is exacerbated by the emission of O₂ from the obligatory combustion reactor placed in-line prior to the reduction reactor. Besides being a nuisance, frequent recharges of the reduction reactor usually require system recalibration; that step costs additional time. Second, chemical reduction by the addition of atomic oxygen to a solid metal implies a reaction that depletes the reagent's active surface. This depletion seems to manifest itself in a time-dependent passivation of the reducing capacity, which recovers with a time constant of minutes. Because the reagent eventually must be replaced, this phenomenon is consistent with the solid state diffusion of oxygen into the bulk metal and a restoration of reducing capacity as bulk metal diffuses to the surface.

Whether or not this explanation is correct, there is clearly a need for an alternate means to rapidly convert organic H to H₂ in a robust, on-line manner. Sofer has presented high temperature as a means to generate H₂ from hydrocarbons, and has shown that high temperature produces a precision of SD(δ D) < 3‰ when implemented off-line in sealed reaction tubes (Sofer & Schiefelbein, 1986). The chemical reactions for hydrocarbons are

thus demonstrating that the reaction proceeds via methane. Above about 1000°C, the latter reaction favors the products and the equilibrium constant is about 100 at 1200°C. The main advantage to this strategy is that it can be used as a limitless reduction source, and that it results in a more robust and low maintenance CF-IRMS system for hydrogen. In our recent work on such a system (Tobias, 1997), an empty alumina tube heated to 1150°C (a safe maximum temperature for the existing furnace in the system) replaces the two on-line chemical reactors. Tests to determine whether the 600°C Pd filter plays any catalytic role in reduction showed that nearly all of the measurable hydrogen signal is due to conversion in the hot pyrolysis furnace. For small hydrocarbons in natural gas mixtures, precisions of isotope ratio measurements are shown to average SD(δ D) < 2‰ because of reduction reproducibility. In addition, isotopic measurement stability was excellent over 24 h, and it appears to be indefinite, dependent only on instrument stability. The disadvantages of the technique are that the maximal pyrolysis temperature varies with compound type. That variability may result in a dif-

fering fractionation of hydrogen isotopes between different compounds. The possible role of heteroatoms giving rise to hydrogen-containing products such as H₂O may also induce fractionation. These problems can be remedied by the inconvenient but effective procedure of calibration for each compound of interest. For chromatography, the PFS offers the advantage that co-eluting contaminants, such as N₂, do not enter the vacuum system along with the analyte hydrogen. In addition, the PFS prevents instrument contamination from unreduced organics due to inefficiencies of thermal degradation with on-line pyrolysis. Ion source contamination may be particularly important for pyrolysis-induced H₂ generation from compounds with heteroatoms.

H. Liquid Chromatography-Combustion (LCC)-IRMS

The major limitation of GC-based systems is their requirement for a volatile and thermally stable analyte. Although nonvolatiles are routinely chemically derivatized prior to GC analysis, most derivatizing agents add extraneous C, H, O, or N to the molecule that cannot be distinguished from the analyte elements by the IRMS, and, therefore, must be taken into account in later calculations to yield accurate analyte isotope ratios. Isotopic fractionations existing at reaction centers can substantially complicate the correction procedure by altering the analyte carbon isotope ratio by an unpredictable degree. These considerations are particularly applicable to biomolecules, which, with few exceptions, require derivatization or simply cannot be made volatile.

The most critical feature for an LC interface is a reliable and reproducible solvent removal prior to analyte introduction to the combustion furnace. Of the several popular approaches to LC-MS interfaces, the moving transport and particle beam devices are the only ones that include an effective desolvation stage prior to introduction to the MS. Prior to its applications to MS, moving transports were used to interface LC to flame ionization detectors (FID), and about 200 were built and sold commercially in the 1960s and 1970s, making it the only interface known to remove solvent well enough for a solvent-sensitive detector. Common to FID and IRMS interfacing is the necessity to remove solvent and to combust analyte at atmospheric pressure. Those requirements are more modest than for organic MS interfacing, which requires a series of vacuum chambers to move the belt into/out of the vacuum system and a means to desorb intact analyte molecules once in the vacuum system. In 1991, Moini and Abramson were able to couple the moving transport interface to demonstrate LC/CRIMS on a conventional single collector organic MS (Moini & Abramson, 1991). We, therefore, initially pursued the moving transport approach to test whether it could be used in a high-precision system.

FIGURE 10. Diagram of a moving belt combustion interface for LCC-IRMS (Caimi, 1995). The continuous loop stainless steel belt is cleaned in a furnace and the LC eluent is pneumatically sprayed onto the belt. The belt passes through a drying oven to remove solvent and a combustion furnace to convert analyte to CO_2 and H_2O , where He carrier sweeps the bands of gas to a Nafion water trap, and to the IRMS. No open split is necessary after the water trap, because the furnace is open to atmosphere and serves as a split.

1. Moving Transports

To extend compound-specific carbon isotope analysis to nonvolatile and thermally labile molecules, we introduced an interface that couples liquid sources, including liquid chromatography (LC), with high-precision combustion-IRMS (LCC-IRMS) (Caimi & Brenna, 1993; 1995). In our original transport system, a solution containing the analyte of interest was coated onto a precleaned moving wire, solvent was reproducibly removed in a drying oven, and the analyte was quantitatively combusted in a CuO/Pt -charged furnace maintained at 850°C . CO_2 and water bands that result from analyte combustion were transferred via a sampling capillary to a Nafion-based water trap. Following water removal, the analyte CO_2 was admitted into the IRMS ion source as a series of bands in He carrier gas. Precision and accuracy for this system were comparable to that of GC-based systems for 50-mg samples. Hardware improvements in the original LC interface system resulted in a sensitivity enhancement of about 300-fold (Caimi & Brenna, 1995). However, a primary limitation of wire-based transport systems is poor sensitivity due to the limited capacity of the wire to capture more than 1–3% of the total analyte. Belts are well-known to retain far greater levels of analyte, particularly in pneumatic spray systems, in which the analyte fans out and is not contained within a small volume.

We describe here in some detail the most recent version of the moving transport interface (Caimi & Brenna, 1995). The transport is a continuous-loop, moving belt that captures an estimated 20% of the total analyte supplied. The prototype moving belt interface is shown in Fig. 10. The belt ($0.08\text{ mm} \times 1.5\text{ mm} \times 115\text{ cm}$) first

passes through a cleaner furnace (900°C) that is purged with a parallel flow of O_2 (15 mL min^{-1}), loops around a pulley, and enters an enclosed coating block. In the block, the analyte solution is converted into a heated (150°C) pneumatic spray that is directed at a 45° angle at one surface of the belt, as described previously in detail (Caimi & Brenna, 1995). Any solvent remaining after the coating process evaporates as the belt subsequently passes through a 12-cm drying oven (200°C) purged with He gas (100 mL min^{-1}). Analyte material deposited on the belt is combusted into CO_2 and H_2O as the belt passes through a CuO/Pt -charged furnace maintained at 850°C . The furnace consists of an unrestricted quartz tube ($2\text{ mm i.d.} \times 20\text{ cm}$ long) with two He purge inlets (leading and lagging flows) maintained at a flow rate of approximately 30 mL min^{-1} . A third port is used to sample the products of combustion and to transport them to a 10-cm long Nafion-based water trap. The dried CO_2 is transferred to the IRMS instrument. All moving belt studies reported here were done in flow injection mode without an in-line chromatography column. Accuracy and precision of the isotope ratio measurements were assessed using multiple injections of isotopically calibrated linoleic acid (2.5 mg) standards with graded $^{13}\text{C}/^{12}\text{C}$ ratios.

Peak-shapes obtained with the wire- or belt-based LCC-IRMS interfaces are comparable, and indicate that band-broadening can be minimized. Compared to the best published wire system (Caimi & Brenna, 1995), detectability in the belt system is improved 40-fold. This improvement can be directly attributed to the ability of the belt to capture a larger proportion of the total analyte compared to the wire systems. Injections of as little as 25 ng of

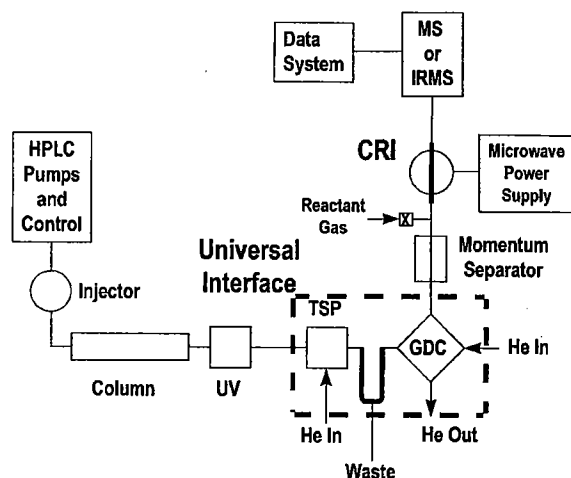

FIGURE 11. Diagram of the LC/CRI/MS interface, redrawn after McLean (McLean et al., 1996). LC eluent flows sequentially through a thermospray pnebulizer (TSP), a solvent trap, a gas diffusion cell (GDC), and a momentum separator to prepare desolvated analyte particles for admission to the chemical reaction interface (CRI) unit. The CRI couples microwave power and reagent gases to convert analyte into small molecules such as CO_2 , which are directed to the IRMS for analysis. The system can also be interfaced to GC.

analyte yield signals clearly discernible from baseline noise, although peaks below the 250-ng level could not be reliably detected or defined by the standard peak identification software. The response of this interface is linear ($r^2 = 0.993$) for analyte loads ranging from 250 ng to 5 mg. Using conventional data reduction, the LCC-IRMS system yields a precision of $\text{SD}(\delta^{13}\text{C}) < 1\text{‰}$ for analyte loads $> 1 \mu\text{g}$. However, as observed previously with both wire systems, with low sample loads, in this case $< 2 \mu\text{g}$, the isotope ratio deviates significantly from the known value that is calibrated against a gas pulse. Biases of this nature have been observed previously in the analysis of low signal levels with GCC-IRMS (Goodman & Brenna, 1994b), but they appear at much lower sample levels. The improvement in GCC-IRMS data with curve-fitting inspired its use for this application, and we have observed similar improvements in LCC-IRMS data quality (Caimi, 1995).

2. LC/Chemical Reaction Interface (CRI)/IRMS

Abramson and coworkers have reported coupling a thermo-spray/particle beam interface with CRIMS to produce an analyte stream from LC (and GC) that is suitable for analysis with a high-precision IRMS (Teffera et al., 1996; Abramson et al., 1996), referred to by the authors as HPLC/CRI/IRMS. Figure 11 is a diagram of the system and is adapted from a non-IRMS publication from the same laboratory (McLean et al., 1996). The eluent from

an LC is directed to a thermospray (TSP) vaporization stage, which volatilizes most of the solvent that condenses on the walls of a desolvation chamber. Analyte particles entrained in a high flow of He are carried through a longitudinal membrane-based gas diffusion cell (GDC). Finally, they pass through a momentum separator, which is the final desolvation stage, and out to a CRIMS interface. The *Universal* interface is the commercial name for the coupled TSP/GDC. Compared to the moving transport, an important advantage of the CRI/IRMS interface is the absence of any mechanical moving parts. Possible concerns are the satisfactory removal of solvent and the absence of nonlinear isotope effects in the plasma chemistry, including reactions that do not proceed to completion.

Replicate injections of $1.2 \mu\text{g}$ of D-ribose into the HPLC introduced about 120 ng into the IRMS to yield precisions of $\text{SD}(\delta^{13}\text{C}) < 1\text{‰}$. There was some small dependence of the isotope ratio on the amount injected between 10 and $20 \mu\text{g}$, a dependence that the authors speculate to be due to a mass interference, possibly $\text{C}_2\text{H}_5\text{O}^+$, arising when CRIMS reactions are not complete. Replicate injections of $2 \mu\text{g}$ chlorophyll-a from two different sources, spinach and algae, produced $\text{SD}(\delta^{13}\text{C}) = 0.5\text{--}0.6\text{‰}$ when calibrated against an internal standard. These two sets of data were found to be significantly different. Solvent removal and isotope effects did not appear to affect the performance in these experiments.

To summarize the state of LC-based CSIA, systems based on two different principles have been demonstrated to yield high-precision results with sample sizes in the one μg range. No commercial versions of these instruments are yet available, although there is some commercial interest in the idea (Brand, 1996). It is probable that considerable work remains to bring LC to the high-precision applications community. It should be noted that tracer applications with more modest precision and accuracy requirements may benefit first from these advances.

TABLE 1. Isotope ratio results from the moving belt interface demonstrate high-precision below 5000-ng load, using either summation or curve-fitting, and systematic bias at lower levels when calibrated against pure CO_2 admitted to the IRMS from a gas tank.

| Load (ng) | Summation | Curve-fit |
|-----------|-------------------|-------------------|
| 5000 | -27.67 ± 0.1 | -27.69 ± 0.10 |
| 2500 | -27.23 ± 0.32 | -26.94 ± 0.08 |
| 1000 | -16.30 ± 0.97 | -16.27 ± 0.86 |
| 750 | -12.67 ± 3.04 | -13.62 ± 2.02 |
| 500 | -13.77 ± 0.49 | -13.63 ± 0.39 |
| 250 | -7.62 ± 1.71 | -7.35 ± 1.1 |

V. POSITION-SPECIFIC ISOTOPE ANALYSIS (PSIA)

Position-specific measurements, that is, measurement of intramolecular isotope ratios, for detection of *natural* variability, have been published but are generally limited only to the most important problems because of the cumbersome chemical degradation and separation steps that are required prior to IRMS analysis. The earliest position-specific research is that of Abelson and Hoering (Abelson & Hoering, 1961), who in 1961 manually isolated the carboxyl position of amino acids via the ninhydrin reaction, and showed the carboxyl group to be enriched relative to the rest of the molecule. They further showed indirect evidence that glycolysis proceeds without isotope discrimination. Almost a decade passed before any further work appeared. A classic article on isotope fractionation established the precise enzymatic step at which acetate carbon is fractionated, resulting in the well-known depletion of ^{13}C in lipids (DeNiro & Epstein, 1977). Pyruvate oxidation to acetate was accomplished by procedures to isolate the carboxyl and methyl carbons of acetate for conventional bulk analysis. Results showed that the isotopic composition of these two positions were very different and that a kinetic isotope effect that discriminates against ^{13}C at the acetate carbon is the depleted site. These results predict alternating ^{13}C abundances along fatty acid aliphatic chains. That prediction has been verified experimentally (Melzer & Schmidt, 1987; Mouson & Hayes, 1982a, 1982b). In related work, Hayes and coworkers analyzed the ^{13}C content of the carboxyl and olefinic C in mono-unsaturated fatty acids from microorganisms (*E. coli* and *S. cerevisiae*), and the refined models of fatty acid metabolism that are based on their position-specific isotopic results (Monson & Hayes, 1982a; 1982b; Volger & Hayes, 1980; Monson & Hayes, 1980). These studies required Schmidt decarboxylation and oxidative ozonolysis to isolate specific carbon positions prior to high-precision determination. A representative review of research up until 1985 can be found (Galimov, 1985), including a discussion of the Galimov theory of biological isotopic fractionation. More recently, Ivlev and coworkers have discussed the relationship between isotopic fractionation in photosynthetic cells and the order of amino acid synthesis (Ivlev, 1986). Most recently, Weilacher et al. investigated intramolecular isotope ratios of C in several positions of caffeine and theobromine in order to study one-carbon metabolism (Weilacher, Gleixner, & Schmidt, 1996). In natural samples, they report a higher enrichment in fused-ring positions 2 and 8, which originate from the tetrahydrofolate pool, than in methyl groups that derive from S-adenosylmethionine ($\delta^{13}\text{C}$: -21.7‰ vs. -39‰); results from chemically synthesized samples showed much smaller average differences. In total, the body of scientific work on

the intramolecular distribution of carbon isotopes clearly indicates that they are indicative of a variety of important physiological processes, and might be routinely analyzed if an instrument were available to do so conveniently. Such an instrument would also facilitate many tracer experiments that are presently accomplished with high enrichments and analyzed using either NMR or organic MS. Until recently, high-precision position-specific measurements were at a similar stage as was CSIA prior to the mid-1970s, and required manual isolation of carbon positions within a molecule prior to analysis. That process is labor-intensive and practically impossible for determining many internal positions (Ivlev, 1991).

The bulk of recent work on pyrolysis-GC has applied the analytical capabilities of GC to nonvolatile, usually intractable, solids, such as high-molecular-weight polymer resins, keragens (Eglinton, 1994), and bacteria. Previously, several groups reported vapor-phase pyrolysis of small organic molecules for qualitative analysis as a possible alternative for GC-MS-based analysis (Dhout, 1961; 1963; Levy & Paul, 1967; Levy, 1967; Fanter, Walker, & Wolf, 1968; Walker & Wolf, 1968). These early studies showed that organic molecules of biological and commercial interest fragmented in a useful and characteristic way, and did so according to predictions of simple free radical fragmentation mechanisms that were elucidated decades earlier for hydrocarbons (Kossiakoff & Rice, 1943; Fabuss, Smith, & Satterfield, 1964). Although pyrolysis-GC systems never overshadowed GC-MS, they suggest a convenient and powerful means for fragmenting organic molecules prior to separation and analysis by IRMS, thereby providing an on-line strategy for the determination of isotope ratios from either groups or individual positions within molecules.

We have recently introduced a strategy for on-line PSIA, based on (1) pyrolytic fragmentation of analyte molecules, (2) measurement of fragment isotope ratios, and (3) calculation of isotope ratios for specific positions and/or for moieties (Corso & Brenna, 1997). Although there is considerable work involving the generation of isotope ratios from pyrolysis products (Mycke, Hall, & Leplat, 1994), there are little data on the prospects for generating reproducible isotope ratios from on-line pyrolysis in a microreactor. We have constructed test systems to evaluate this question for pentane and methyl palmitate (Me16:0).

The initial test system did not allow for separation prior to pyrolysis and admitted injected analyte into a pyrolysis furnace. *Headspace* pentane (about $10\text{ }\mu\text{L}$, $<300\text{ ng}$) was injected into the pyrolysis chamber at temperatures ranging from $100\text{--}500^\circ\text{C}$. Pyrograms and results are shown in Fig. 12 and Table 2. Below about 380°C , no fragmentation is observed. At 420°C , partial pyrolysis is observed, and the products are strong, reproducible peaks, as shown in Fig. 12(b). Figure 12(d) shows results at

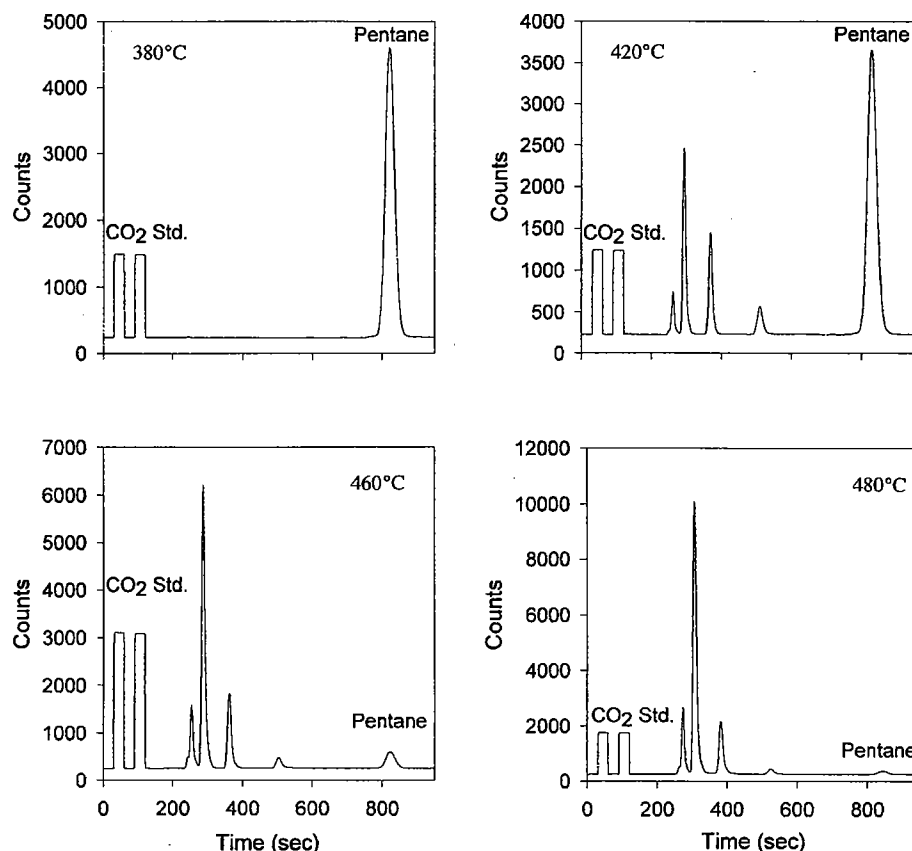

FIGURE 12. Results from analysis of pentane by PSIA at various pyrolytic temperatures. As the temperature is increased, pentane undergoes increasing degrees of fragmentation. Four fragment peaks are observed, corresponding to C1, C2, C3, and C4. Isotope ratios derived from these peaks are shown in Table 2 to be highly precise.

480°C, where pentane is almost quantitatively pyrolyzed and the products are the major peaks in the spectrum. Assuming no rearrangements, the four fragments correspond to C1, C2, C3, and C4, eluting in that order.

Table 2 presents the results of replicate analyses of the pyrolysis fragment peaks at 420°C. These data show that on-line pyrolysis is highly reproducible and that the

subsequent chromatography has sufficient quality for IRMS. The average precision is $SD(\delta^{13}C) < 1\%$, and is, therefore, sufficient to follow isotope ratio changes relevant in nature, even with this preliminary system. Some of the mean isotope ratios among the fragments are statistically different, indicating that the system is sensitive to changes in the isotope ratio. Methane is often observed to be the isotopically lightest hydrocarbon in nature. Progressively larger hydrocarbon chains increase in ^{13}C content up to C₃ or so (Baylis, Hall, & Jumeau, 1994).

Because this system demonstrated on-line pyrolysis to be reproducible, we constructed a second system, shown in Fig. 13, with a front end very similar to that of Levy and Paul in a tandem GC configuration (Levy & Paul, 1967). The principal additions to the previous system were: (1) the addition of a separation GC with appropriate valving to select a single purified peak into the pyrolysis chamber, and (2) the addition of a valve in the second GC to permit separated fragments to be admitted to an organic MS for structure analysis of pyrolysis products to verify

TABLE 2. Precision of carbon isotope ratio determinations from pyrolytic fragments of pentane.

structures predicted by theory and to perform labeling experiments to rule out any rearrangement. The test compound Me16:0 was purified in a first GC, and fragmented pyrolytically. The fragments were separated in the second GC, and were analyzed by either an ion trap MS, or an IRMS for high-precision isotope ratio analysis. Pyrolysis of Me16:0 yields two series of fragments that differ by one C up to the C₁₇ parent; structures are shown in Fig. 14. Data from labeling studies using [1-¹³C], [Me-¹³C], [16-¹³C], and [Me, 16-¹³C]-Me16:0 indicate no rearrangement of carbon due to the pyrolysis process. The difference in ¹³C atom fraction between consecutive fragments corresponds to the ¹³C atom fraction of the additional carbon position in the larger molecule, and can be calculated as a weighted difference between the two fragments. The reproducibility of fragment isotope ratios is SD(δ¹³C) = 0.3‰, and calculations of the isotope ratio of the carboxyl carbon were in good agreement with dilution data.

Data obtained for fragmentation at different temperatures showed that pyrolysis-induced fractionation was nearly insensitive to temperature. This observation leads directly to the conclusion that pyrolysis conducted at a single temperature should result in fragments with isotope ratios that are readily calibrated against standards. Results thus far indicate that controlled pyrolysis can be conducted on-line and can produce single bond breakage, stabilization, and isotopically representative fragments of carbon. The absence of any measurable rearrangement or major fractionation shows the approach to be applicable to position-specific studies of carbon at natural abundance or very low enrichment. Both of the systems that we have reported should be useful for PSIA, with the simpler system supe-

rior for purified small molecules, where fragmentation is known or is relatively simple; and the more complex system is appropriate for complex mixtures and larger, uncharacterized molecules.

VI. NOTATION AND ELEMENTARY CALCULATIONS

Because the historical development of CF-IRMS focused on isotope variability due to natural processes, the notation and conventions used in this field derive from and apply to the long history of non-CSIA based on the dual inlet, which typically deals with variability over a very limited range of isotope ratios. As applications increase involving high enrichments characteristic of artificial isotope enrichment (Goodman & Brenna, 1992; Cunnane et al., 1995; Carnielli et al., 1996; Brenna, 1997) or using very low enrichment compounds derived naturally (Tissot et al., 1990; Dammelmair et al., 1995), there is a need to review basic relationships. In this section, we bring together notations and relationships used in natural variability research coupled to relationships derived to calculate useful quantities for tracer applications. For simplicity, we consider the case of C, but all equations apply directly to other elements with simple substitution.

A. Delta Notation

The delta notation was first formally defined by McKinney et al. (McKinney et al., 1950; Hayes, 1983), and is the

ω-Monounsaturated Methyl Ester Series

α-Olefin Series

FIGURE 14. Structure of stable pyrolytic fragments from methyl palmitate. The hydrocarbon chain breaks between each C—C bond, starting at C3—C4. Unsaturation is introduced into each fragment by ejection or rearrangement of H. There is no detectable scrambling of C in the cleavage or stabilization process as predicted for the free radical-mediated mechanism, although rearrangement is predicted for the hydrogens. These fragments are isotopically representative of the original molecular isotope distribution. (Reprinted with permission from PNAS 94:1049–1053, Fig. 3, February 1997, copyright 1997 National Academy of Sciences, U.S.A.)

conventional means for expressing high-precision isotope ratios. It is defined as the relative difference in parts per thousand between the sample isotope ratio and an isotope ratio of an international standard. In the case of C, the standard is PeeDee Belemnite (PDB), expressed as

$$\delta^{13}\text{C}_{\text{PDB}} = \left(\frac{R_{\text{STD}} - R_{\text{PDB}}}{R_{\text{PDB}}} \right) \times 1000 = \left(\frac{R_{\text{SPL}}}{R_{\text{PDB}}} - 1 \right) \times 1000 \quad (8)$$

with

$$R_x = \frac{[^{13}\text{C}]}{[^{12}\text{C}]}, \quad (9)$$

where $[^{13}\text{C}]$ and $[^{12}\text{C}]$ are the abundances of the respective isotopes in the sample or PDB, $R_{\text{PDB}} = 0.0112372 \pm 0.0000090$ (Craig, 1957), and where the latter $\delta^{13}\text{C}_{\text{PDB}}$ form is more convenient for calculations. In practice, abundances from samples and working standards calibrated against PDB are used to calculate δ_{WS} , and the following form is used to convert δ_{WS} to $\delta^{13}\text{C}_{\text{PDB}}$:

$$\delta_{\text{PDB}}^{\text{SPL}} = \delta_{\text{WS}}^{\text{PDB}} + \delta_{\text{SPL}}^{\text{WS}} + \frac{\delta_{\text{PDB}}^{\text{PDB}} \delta_{\text{SPL}}^{\text{WS}}}{1000}, \quad (10)$$

where superscripts refer to the reference ratio. A very useful brief discussion of international standards is available (Ehleringer & Rundel, 1988).

It is frequently necessary to discuss the precision associated with IRMS measurements, often in the context of analytical development. For this purpose, we use $\text{SD}(\delta^{13}\text{C})$ as the standard deviation (root mean square deviation) expressed in $\delta^{13}\text{C}$ units.

B. Atom Fraction (Percent) Notation

In tracer studies, it is more convenient to express isotope data in terms of isotope concentrations rather than the relative ratio form of $\delta^{13}\text{C}$. For high-precision results, it is first necessary to calculate $\delta^{13}\text{C}$ from ion current ratios of sample and standard, from which calibrated isotope ratios, R_x , can be extracted. Atom fractions (F_x) and atom percents (AP) can be calculated according to the following:

$$F = \frac{^{13}\text{C}}{^{12}\text{C} + ^{13}\text{C}} = \frac{R_s}{1 + R_s}; \quad AP = F \times 100. \quad (11)$$

Atom percent excess (APE) is expressed in two different ways:

$$APE = (AP)_E - (AP)_B \quad (12)$$

OR

$$APE' = \frac{R_E - R_B}{1 + (R_E - R_B)} \times 100. \quad (12b)$$

By definition, APE is given by the difference between AP for enriched samples and AP at background (Coleman & Fry, 1992), and reflects the percentage of labeled atoms in excess of natural background. The alternative formulation (APE') is widely used (Wolfe, 1992), but the quantities are not analytically equivalent, even though they yield similar values near natural abundance.

To illustrate the difference between the two formulations for APE and other means for expressing isotope concentration, we consider a range of enrichments from natural abundance to near 100% ^{13}C as shown in Table 3. The sixth column shows that the difference between APE and APE' is experimentally very small near natural abundance. At high enrichment, APE approaches $98.8888 = 100 - F_{\text{PDB}}$, and APE' approaches 100. Thus, APE' expresses the percentage between baseline and maximal enrichment, so that a compound with 100% ^{13}C is equivalently expressed as $APE' = 100$. Table 3 also shows how $\delta^{13}\text{C}$ approaches infinity at high enrichments, making it very cumbersome for calculations involving highly enriched tracers. To preserve most of the advantages of this notation, we have proposed (Corso & Brenna, 1997) an alternative formulation based on isotope fractions as follows:

$$\begin{aligned} \phi^{13}\text{C}_{\text{PDB}} &= \left(\frac{F_{\text{SPL}} - F_{\text{PDB}}}{F_{\text{PDB}}} \right) \times 1000 \\ &= \left(\frac{F_{\text{SPL}}}{F_{\text{PDB}}} - 1 \right) \times 1000. \quad (13) \end{aligned}$$

This notation has the advantage that its units are nearly identical to the common $\delta^{13}\text{C}$, relative parts per thousand, and increasing linearly up to 100% ^{13}C . The last two columns of Table 3 show $\phi^{13}\text{C}$ and the difference between $\delta^{13}\text{C}$ and $\phi^{13}\text{C}$ around natural abundance and at high enrichments. Near natural abundance, the difference is sufficiently small so that it will be discernible only with very precise CF measurements that are somewhat removed from the isotope ratio of the international reference standard. At highest enrichments, $\phi^{13}\text{C}$ rises linearly rather than approaching infinity like $\delta^{13}\text{C}$. The major advantage of $\phi^{13}\text{C}$ becomes apparent in calculations involving mixing of isotope pools requiring the mass balance equation.

TABLE 3. Comparison of various notations to express high-precision isotope data, using carbon as an example.

| $\delta^{13}\text{C}$ (‰) | R | F | APE | APE' | $APE-APE'$ | $\phi^{13}\text{C}$ (‰) | $\delta-\phi$ |

C. Mass Balance

The fundamental relationship used for many years in high-precision work to determine relative contributions of two or more carbon sources to a pool is mass balance, also referred to as the *Master Equation*. This two-part equation is often cast as follows:

$$\delta_A m_A + \delta_B m_B = \delta_C m_C \quad (14)$$

$$m_A + m_B = m_C \quad (15)$$

Substituting the definition of δ into (14) gives

$$\frac{R_A - R_{PDB}}{R_{PDB}} m_A + \frac{R_B - R_{PDB}}{R_{PDB}} m_B = \frac{R_C - R_{PDB}}{R_{PDB}} m_C \quad (16)$$

Collecting terms, we have

$$R_A m_A + R_B m_B = R_C + R_{PDB}[m_A + m_B - m_C] \quad (17)$$

Noting that the bracketed term equals 0 from (15), we have

$$R_A m_A + R_B m_B = R_C m_C \quad (18)$$

which demonstrates that (14) is equivalent to a weighted sum of isotope ratios. This relation is not analytically correct, as is evident from the cross-term of (10). It is isotope concentrations, or conventionally expressed atom fractions or atom percents, to which mass balance applies. We have

$$F_A m_A + F_B m_B = F_C m_C \quad (19)$$

where F_x is the atom fraction of "x" given by

$$F_x = \frac{[^{13}\text{C}]}{[^{12}\text{C}] + [^{13}\text{C}]}; \quad F = \frac{R}{1 + R} \quad (20)$$

In the neighborhood of natural abundance for carbon, the error introduced by using (14) instead of (20) is negli-

gible, as evidenced by the common use of expressions of "delta-over-baseline," $DOB = \delta_{\text{ENRICHED}} - \delta_{\text{BASELINE}}$. However, for studies involving enriched material, R results in large deviations as enrichment goes to $^{13}\text{C} = 100\%$. We can also cast an analytically correct mass balance equation in *per mil* (‰) using $\phi^{13}\text{C}$, as follows:

$$\phi^{13}\text{C}_a m_a + \phi^{13}\text{C}_b m_b = \phi^{13}\text{C}_c m_c \quad (21)$$

This equation directly yields analytically correct isotope concentrations in parts per thousand units without cross-terms and without resort to conversions after manipulations. For simplicity and to follow convention, we will use Eq. (19); however, all results can be easily adapted to the $\phi^{13}\text{C}$ notation.

D. Tracer Studies Using High-Precision CSIA

There is an increasing interest in the use of high-precision CSIA in tracer studies. Several years ago, we demonstrated that increasing enrichment of precursor compounds produces significantly improved detection limits, with highest enrichment, uniformly labeled compounds producing the highest sensitivity (Goodman & Brenna, 1992), unlike organic GC/MS where increasing label has no general effect on detection limits.

Detection limits are defined for most analytical techniques in terms of a particular threshold S/N ratio obtained upon analysis of a minimal amount of sample, with units often expressed as mean/SD. High-precision implies measurement of strong signals; thus, detection limits in these terms are seldom if ever quoted for IRMS instruments. Rather, there is a minimal sample size required to yield a threshold precision, and sample size is quoted on a per mol or per gram element basis. For example, analytical performance for CF carbon analysis might be quoted as 10 ng C to produce a precision of $SD(\delta^{13}\text{C}) < 0.3\%$.

Tracer detection limits can be defined in terms of the least significant difference (LSD) above baseline that can be declared significant, as has been discussed previously

FIGURE 15. Theoretical relationship between tracer-tracee ratio and measured $\delta^{13}\text{C}$, calculated assuming an endogenous value of $\delta^{13}\text{C} = -30\text{‰}$ and a tracer ^{13}C atom fraction = 1, using the mass balance equation. This plot shows the increase in isotope ratio expected with increasing tracer-tracee ratio. If the analytical precision, including all workup steps, is no worse than $\text{SD}(\delta^{13}\text{C}) < 0.5\text{‰}$ and the baseline does not contribute appreciable variability, then dilutions of up to 10^5 can be detected by this tracer technique.

(Brenna, 1994). As in any analytical technique, the LSD depends on the measurement precision, which in turn depends on sample size. Choosing a sample size of one nmol carbon, which should easily produce a precision of $\text{SD}(\delta^{13}\text{C}) = 0.4\text{‰}$, we use mass balance to give a plot of $\delta^{13}\text{C}$ vs. the tracer:tracee ratio (T/T) in any pool. To construct the plot shown in Fig. 15, we assume that the endogenous compound has an isotope ratio corresponding to $\delta^{13}\text{C} = -30\text{‰}$, and that the labeled compound is uniformly labeled with an atom fraction $F = 1$. The plot shows that a 1‰ increase above baseline corresponds approximately to a 1:100,000 dilution, indicating that this value is the limiting dilution for high-precision measurements.

It is worth noting that the background variability depends on the external precision of the instrument and on the natural variability of the backgrounds under study. For instance, the external precision of GCC-IRMS can reliably be obtained at a level of $\text{SD}(\delta^{13}\text{C}) < 0.4\text{‰}$, which sets a lower bound on detectability. However, the two photosynthetic pathways, commonly designated C3 and C4, fractionate carbon isotopes to differing degrees, resulting in differences of about 20‰ in materials derived from these two sources. Isotope ratio measurements in animals whose source of carbon is ultimately derived from plants using both photosynthetic pathways will vary in a complex way between these extremes. Instrumental external precision in these experiments may be a minor factor affecting detection limits if diet is variable and uncontrolled.

E. Mass Balance: Pool Mixing

High-precision is most easily achieved near natural abundance for a variety of reasons, including similarity of peak-shapes among the various detection channels and closeness for calibration against standards. For this reason, it is necessary to dilute highly enriched dose material to facilitate high-precision determination. The mass balance equation for dilution of a chemically pure, highly enriched species with the chemically identical natural abundance species is

$$F_N m_N + F_L m_L = F_T m_T; \quad m_E + m_L = m_T, \quad (22)$$

where N refers to natural abundance diluent, L is a highly enriched labeled material, and T is total. We define dilution as

$$D = \frac{m_L}{m_N + m_L} = \frac{m_L}{m_T}; \quad m_L = D m_T. \quad (23)$$

We wish to plot F_T vs. D , so

$$F_T = F_N \left(\frac{m_N}{m_T} \right) + F_L \left(\frac{m_L}{m_T} \right) \quad (24)$$

$$F_T = F_N(1 - D) + F_L D \quad (25)$$

$$F_T = F_N + D(F_L - F_N). \quad (26)$$

Equation (26) shows that a plot of F_T vs. D yields a y-intercept of F_N and a slope of $F_L - F_N$. It further shows that the concentration of the original solutions is not required for these calculations. Errors associated with the determination of F_N and F_L depend only on the determination of F_T and the quality of quantitative volume dilutions.

The last point is worthy of emphasis. The precision and accuracy of F_L determination is limited by the precision and accuracy of the quantitative dilution. Because highly enriched samples are difficult to analyze precisely by IRMS (or other means), there is the temptation to dilute with natural abundance material to bring the isotope ratio into an easily measured range. However, the precision of the IRMS measurement will be lost if the dilution is not of the same precision. An example is the dilution of a body fluid, for instance milk, originally with a $\delta D > 2000\text{‰}$. Milk is highly variable in its solute content, which conversely can be thought of as being highly variable in its water content. Simple gravimetric dilution with water of known isotope ratio will not yield a high-precision dilution factor, because the weight of water in the milk is not known. Weight of water can be characterized with precision required for D analysis (Brenna & Yeager, 1995) with coefficients of variation consistently less than 0.1% by gravimetric determination of weight loss after very careful drying. However, this precision may not be suffi-

cient to preserve precision for $\delta^{18}\text{O}$ measurements. Drying also does not take into account the presence of volatiles that are not in isotopic equilibrium with the analyte.

Introduction of labeled molecules into an endogenous pool results in elevated isotope ratio. If there is no covalent modification of the tracer, and no labeled atoms are displaced or altered in isotope ratio, then the mass balance equation to describe this process takes the form:

$$F_T m_T = F_L m_L + F_E m_E; \quad m_T = m_L + m_E \quad (27)$$

or

$$F_T = F_L \left(\frac{m_L}{m_T} \right) + F_E \left(\frac{m_E}{m_T} \right) \quad (28)$$

Because

$$\frac{m_E + m_L}{m_T} = 1 \quad (29)$$

we have

$$F_T = F_L \left(\frac{m_L}{m_T} \right) + F_N \left(1 - \frac{m_L}{m_T} \right), \quad (30)$$

where we have replaced the subscript "N" with "E" to refer to *endogenous*. Rearranging yields the final result,

$$\frac{m_L}{m_T} = \frac{F_T - F_E}{F_L - F_E} = \frac{AFE}{F_L - F_E}, \quad (31)$$

where $F_T - F_E$ has been replaced by atom fraction excess (AFE). Equation (22) indicates that the ratio of tracer to total material (tracer:tracee ratio, " T/T ") is given by the ratio of the difference in enrichment between the tracer and endogenous divided by the difference between the final and endogenous enrichments. When $F_L = 1$, as it does for highly enriched compounds, to a good approximation $F_L \gg F_E$, $F_L - F_E \approx F_L = 1$ and

$$\frac{m_L}{m_T} = AFE = \frac{APE}{100}, \quad (32)$$

which shows that the tracer:tracee ratio is approximated by the atom fraction enrichment, or equivalently the atom percent enrichment divided by 100.

In tracer experiments, it will often be desirable to calculate the quantity of a product derived from a different tracee compound. The situation is most easily illustrated by means of an example. Fatty acids play critical roles in many physiological processes. The level of interconver-

sion of fatty acids from dietary precursors is frequently of importance to determine adequate dietary levels and partitioning between pathways. Consider the case of the conversion of α -linolenic acid ($\text{C}_{18}\text{H}_{30}\text{O}_2$, "18:3"), a straight chain triunsaturated fatty acid, to the product docosahexaenoic acid ($\text{C}_{22}\text{H}_{32}\text{O}_2$, "22:6") by the addition of four carbons and the introduction of three additional double bonds. A dose of highly enriched 18:3 is metabolized to 22:6 by the addition of 4 carbons whose isotope ratio is in the range of the endogenous 22:6. Hence, the isotope ratio of labeled 22:6 will be lower than the dose with this endogenous dilution by a factor of 4/22, and the application of the previous equations to determine T/T will result in an error of this magnitude. We can derive an expression to account for this dilution using mass balance to arrive at the total mol of labeled 22:6 molecules. The mass balance equation takes the form:

$$F_T m_T = F_E m_E + m_L (\alpha F_L + \beta F_E); \quad m_T = m_E + m_L; \quad \alpha + \beta = 1, \quad (33)$$

where the F_T , m_T , F_E , and m_E are defined for the product, and F_L is the atom fraction of the *precursor*, because it refers to the labeled carbons. α is the number of mol of carbon per mol precursor compound divided by the mol carbon per mol product. In our example, there are 18 mol of C per mol 18:3, 22 mol C per mol 22:6, so $\alpha = 18/22$. β can be interpreted as the mol of endogenous carbon added to each mol of labeled product; in our example, 4/22. $F_L = 1$ if 18:3 is 100% ^{13}C . Dividing the equation by m_T , collecting terms, and solving for T/T , we have

$$\frac{m_L}{m_T} = \frac{F_T - F_E}{\alpha F_L + \beta F_E - F_E} = \frac{F_T - F_E}{\alpha F_L + F_E(\beta - 1)}. \quad (34)$$

Recognizing that $\alpha + \beta = 1$ can be rearranged to yield $\beta - 1 = -\alpha$, substituting, and collecting terms, we arrive at the final result:

$$\frac{m_L}{m_T} = \frac{1}{\alpha} \left(\frac{F_T - F_E}{F_L - F_E} \right) = \frac{1}{\alpha} \left(\frac{AFE}{F_L - F_E} \right). \quad (35)$$

This equation is identical to the T/T expression in Eq. (31), with $1/\alpha$ serving as a proportionality constant. In our example, m_L/m_T is the molar fraction of 22:6 that is labeled with 18:3. If all the 22:6 were derived from 18:3, and 18 of each 22 carbons were labeled, then $m_L/m_T = 1$.

Because CSIA does not detect isotopomers, it is not possible to distinguish between product molecules resulting from simple carbon addition to the precursor from molecules labeled by catabolism and *de novo* synthesis. In our example, it is thought that 18:3 oxidation to acetate, and subsequent synthesis to fatty acids and other com-

pounds is an important physiological mechanism for the brain. Although 22:6 cannot be synthesized from acetate, labeled acetate could be used for elongation of endogenous 18:3 to yield 22:6 labeled in only two positions rather than 18. This phenomenon is observed for the synthesis of saturated fatty acids from a number of unsaturated precursors (Sheaff et al., 1996). Hence, T/T in this context can be best thought of as “dose-equivalents.” Context will often suggest a most prominent form so that little ambiguity may remain.

F. Dilution Space

Calculation of dilution space requires the determination of the initial enrichment of the dose. For tracer experiments, the dose enrichment is very high compared to the endogenous pool and must, in general, be diluted prior to high-precision determination.

Two mass-balance equations can be used to derive the relationship between the relevant enrichments and the weights of the doses and diluents. The mass-balance equation relating dose and body pools is

$$F_T m_T = F_L m_L + F_E m_E, \quad (36)$$

where the subscripts T , L , and E refer to *Total*, *Label*, and *endogenous*, respectively. The mass-balance equation for the dilution of an aliquot of dose with natural abundance material can be written:

$$F_{dD} m_{dD} = F_D m'_D + F_d m_d \quad (37)$$

with the subscripts dD , D , and d referring to *diluted Dose*, *Dose*, and *diluent*, respectively, and the prime of m_D distinguishes the quantity of dose used for dilution from that of Eq. (36). If we make the assumption that $m_T \sim m_E \gg m_L$ in (36) and that m_{dD} approximates m_d in (37), then we can replace m_T with m_E in (36) and m_d with m_{dD} in (37). Rearranging (37) we have

$$F_D = \frac{m_{dD}(F_{dD} - F_d)}{m'_D}. \quad (38)$$

Substituting F_D into (36), and recognizing that $m_D = W_D/M_D$, where W is weight and M is the molecular weight, we have

$$F_T m_e = \left(\frac{m_{dD}(F_{dD} - F_d)}{(W'_D/M_D)} \right) \left(\frac{W_D}{M_D} \right) + F_e m_e, \quad (39)$$

with M_D canceling. Rearranging, we find

TABLE 4. Chronology of selected developments in Continuous Flow (CF) IRMS instrumentation.

$$m_e = \frac{F_{dD} - F_d}{F_T - F_E} \left(\frac{W_D}{W'_D} \right) \left(\frac{W_{dD}}{M_{dD}} \right). \quad (40)$$

This final equation yields the very convenient result that the molecular weight of the highly enriched dose cancels. This relationship is very convenient, because the molecular weight for an enriched compound in general cannot be calculated from natural abundances because the abundance of “unlabeled” elements may be affected by the isotope purification procedures. The dilution space depends on the relative enrichments of the body pool and the dilution pool, the weights of the enriched material in each space, and the diluent. The inverse of this equation can also be viewed as a scaling of the enrichment by the dose level, and is particularly convenient for plotting more than one isotope enrichment on the same scale, as has been recommended by Coward for doubly labeled water studies (Prentice, 1988).

VII. CONCLUSIONS

In Table 4, we have compiled a chronology of developments in CF-IRMS for reference and to illustrate the state-of-the-science. There remain many fundamental instrumentation advances, most notably development leading to the routine analysis of H isotopes after chromatographic separation, the routine application of liquid separation-based techniques to IRMS, and the application of PSIA to detect intramolecular variations in isotope ratio. The CF techniques now routinely solving application problems are elemental analyzer determination of C and N, GC applications for C, analysis of isotopes in water using the equilibration techniques, CO₂ breath analysis, and trace gas analysis. Additional penetration into the myriad of applications for IRMS awaits instrument refinements and commercialization. Continuing improvements in precision and sensitivity of CF-IRMS, along with automation, expand its applicability and ensure that it continues as an important and unique tool of analytical mass spectrometry.

Received 10 June 2003; received in revised form 8 August 2003; accepted 12 August 2003

Abstract

High-precision isotope ratio mass spectrometry (IRMS) systems are equipped with digitizers that deliver effective maximum digitization depths of 16 to 24 bits; however, there are no analyses of the proper board depth required to retain high precision in continuous-flow techniques. We report an experimental and theoretical evaluation of quantization error in continuous-flow IRMS (CF-IRMS). CO₂ samples (100 pmol–30 nmol) were injected into a gas chromatography combustion IRMS system (GC-CIRMS). The analog signal was digitized by high precision, 24-bit ADC boards at 10 Hz, and was post-processed to simulate 12, 14, and 16-bit data sets. $\delta^{13}\text{C}_{\text{pdb}}$ values were calculated for all data sets by the conventional “summation” method or by curve-fitting the chromatographic peaks to the exponentially modified Gaussian (EMG) function. Benchmarks of S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) = 0.3, 0.6, and 1.0‰ were considered to assess precision. In the presence of significant quantization noise, curve-fitting required several-fold less CO₂ than the summation method to reach a given benchmark. We derived an equation to describe the theoretical limitations of precision for the summation method as a function of CO₂ admitted to the source and the step size of the boards. Theory was in close agreement with the observed lower limit of precision for the simulated 16-bit data set. Curve-fitting achieved a precision of S.D. <0.3‰ for injections 20-fold smaller than summation for CO₂ samples collected on an IRMS with 16-bit resolution. By mitigating the impact of quantization noise, curve-fitting expands the dynamic range within a single run to include lower analyte levels, and effectively reduces the need for high pumping capacities and high precision ADC boards.

1. Introduction

Isotope ratio mass spectrometry (IRMS) coupled to a gas chromatography–combustion interface (GC–C) can routinely measure relative differences in $^{13}\text{C}/^{12}\text{C}$ isotope ratios to a precision of few parts per million for samples containing 10 ng of sample or less

[1,2]. GC–CIRMS data consists of three concurrent chromatographic traces ($^{44}\text{CO}_2$, $^{45}\text{CO}_2$, $^{46}\text{CO}_2$) from three detectors operated in parallel. Achieving high precision requires careful and consistent definition of background levels and peak integration for all three traces. Most commonly, peak areas are integrated by the “summation” method. The start and end of a peak are detected, and the background is described as a square or trapezoidal area beneath the peak. Raw data are summed over the length of the peak, and the background area is subtracted. Ricci et al. [3] described two

general methods for determining the background using summation; the “individual summation” method, in which the background is defined by connecting low points on either side of the peak, and the “dynamic summation” method, in which low points are connected throughout the chromatogram regardless of the location of peaks.

All IRMS instruments use digitizers to convert analog signal from Faraday cups to digital data, which must be processed to yield isotope ratios. The precision of a digitizer is expressed in terms of bits, where an N -bit board has 2^N steps over a given range. As an example, a 16-bit board has $\sim 65\,000$ steps; if the board has a range of 0–10 V, then the step size of the board is ~ 0.15 mV. The rounding of a continuous signal to discrete steps introduces noise, which is referred to as quantization error or “bit noise”. This effect is shown graphically in Fig. 1, where simulated Gaussian peaks of 24, 16, 14, and 12-bit resolution are presented. At high resolution (24 bits), no quantization noise is noticeable, and the peak appears as a smooth trace. As the resolution decreases, steps become obvious, and the shape of the peak deteriorates. The quality of data reduction in continuous-flow IRMS must depend at least in part on the digitizer depth because the intensity level established for peak start and stop depends on this parameter. As depth decreases, the intensity of

the background is, in general, less well represented by the intensity levels of the peak’s start and stop points. There are no analyses available that establish the relationship between isotope ratio precision and digitization depth.

The effect of digitization depth on precision and accuracy is inextricably linked to data reduction algorithms. The reproducibility of the summation background correction depends in part on the two points that anchor the background line under the peak; imprecision in the measurement of either point multiplies through the entire length of the background segment connecting the points. In the presence of a simple linear background, a background line is easily drawn between any two points on either side of the peak, as shown in Fig. 2a. Chemical noise due to column bleed or contaminant peaks may cause inaccuracy in defining the background, but such noise is usually correlated in all three traces. This covariance may mitigate the effects of chemical noise on the calculated isotope ratio. However, in the case of quantization error, as shown in Fig. 2b, the magnitude and direction of error is uncorrelated among the three traces, and this then poses a special case. Our previous work has shown that peak integration by curve-fitting improves precision and accuracy in cases of low signal-to-noise [4] and overlapping peaks [5]. Background correction

Fig. 1. A simulation of a Gaussian signal collected by ADCs of various resolutions (24, 16, 14, and 12 bits) and quantization errors. At 24-bit resolution, quantization error is not visible, and the peak appears as a smooth trace. At 16 bits, bit noise is evident primarily at the base of the peak. At 12-bit resolution, the signal is barely recognizable as a Gaussian shape.

Fig. 2. Simulated chromatographic peaks in the presence of a linearly rising background (a) without and (b) with quantization error. In the presence of quantization error, the true background may fall anywhere within the arrows. Without quantization error background is easily and accurately achieved by connecting points on either side of the peak.

in curve-fitting is not constrained to the actual values represented by the discrete digitization levels, and we hypothesized that it may not be as sensitive to quantization error as summation.

Quantization error is typically not dominant in GC–CIRMS when high precision IRMS data acquisition systems use sufficiently deep digitization boards and signals are sufficiently strong. Noise from other sources, such as chemical noise, is greater than the step size of the digitizers. However, quantization error may become important in two specific situations: (a) in data reduction of minor peaks in a chromatogram where there are fewer steps between baseline and peak top, and (b) when low precision digitizers are used, as is common in low cost IRMS instruments designed primarily for measurements of high abundance samples, such as CO_2 in breath tests. In addition, these systems usually have lower pumping capacity, which limits the flow rate that the IRMS source accepts. The lower inlet flow rates result in smaller signals for equivalent analyte abundance via higher split ratios, making quantization error more prominent. In this report, we evaluate quantization error theoretically and experimentally to determine the limiting the precision achieved by the conventional summation algorithm and by curve-fitting.

2. Experimental

2.1. Instrumentation

A Varian 3400 GC system was coupled via a combustion furnace to one of two gas IRMS instruments:

(a) a FinniganMAT 252 (FMAT252) run in high linearity mode, or (b) an Analytical Precision Products 2003 (APP2003). Both IRMS systems were operated with a source pressure of 1×10^{-6} Torr and had an absolute sensitivity of ~ 5000 mol/ion (1 Torr = 133.322 Pa). The GC–C system is described in detail elsewhere [6]. Briefly, the effluent from the capillary column (60 m \times 0.32 mm, 0.25 μm , BPX70; SGE, Austin, TX, USA) is directed to a combustion furnace filled with CuO and held at 850 $^\circ\text{C}$, and dried in a Nafion water trap before admittance to the IRMS system through an open split. Since CO_2 gas was injected as a sample, the combustion step was not necessary, but was retained in the system to increase the verisimilitude to real GC–CIRMS operating conditions. The FMAT252 has differential pumping and a higher overall pumping capacity, while the APP2003 has only a single turbopump. As a result, the FMAT252 can tolerate higher inlet flow rates. The open split of the FMAT 252 accepted 0.2 ml/min (split ratio = 8.4:1), and the open split of the APP2003 accepted 0.07 ml/min (split ratio = 24:1).

CO_2 (Airgas East, 99.9%) injections were performed by hand consecutively. The split ratio and the injection size were varied to yield between 100 pmol and 30 nmol on column. Four or five replicates were performed for each injection size. The moles of CO_2 in each injection were approximated by assuming ideal gas conditions.

Data was collected on the FMAT 252 using SAXI-CAB [7], a laboratory-built LabVIEW-based [8] data acquisition system employing National Instruments (Austin, TX, USA) 435 \times digitizers yielding

24 bits operating at 10 Hz. Data were collected on the APP2003 using the vendor-supplied 16-bit, 10 Hz data acquisition system. Both systems simultaneously monitored the $m/z = 44$, 45, and 46 cups with >99% duty cycle.

2.2. Data processing

Before data reduction, data collected from the FMAT 252 at 24 bits was rounded on all three traces to simulate 16-, 14-, and 12-bit data sets. The head amplifiers have a maximum signal of 10 V (33 nA for $m/z = 44$), so the step size, Δ , for a given board depth was calculated as:

$$\Delta = \frac{10 \text{ V}}{2^{\text{bits}}} \quad (1)$$

We created simulated data sets by rounding data points to the nearest step:

$$\text{data(quantized)} = \text{round} \left[\frac{\text{data(raw)}}{\Delta} \right] \Delta \quad (2)$$

where, the *round* function rounds the input to the nearest whole number.

The 16-bit data from the APP2003 was used without modification. All data sets were processed using SAXICAB by either the individual summation method or by curve-fitting. The individual summation method used by SAXICAB was adapted from Ricci et al. [3]. Starts and stops of peaks were determined with a slope sensitivity of 0.3 nA/s. The lowest point 2 s before and 2 s after the peak limits were located, and a straight line was drawn between the two points to define the background. In the curve-fitting algorithm, the traces were fit to exponentially modified Gaussian (EMG) functions using the Levenberg–Marquardt algorithm. Mathematical details of the EMG function can be found elsewhere [9].

High-precision isotope ratios are expressed in the delta (‰) notation:

$$\delta^{13}\text{C}_{\text{pdb}} = \frac{{}^{13}R_{\text{spl}} - {}^{13}R_{\text{pdb}}}{{}^{13}R_{\text{pdb}}} \times 1000 \quad (3)$$

where ${}^{13}R_x$ is the ratio of ${}^{13}\text{C}$ to ${}^{12}\text{C}$, SPL refers to the sample, and PDB refers to the international standard, Pee Dee Belemnite, where ${}^{13}R_{\text{pdb}} = 0.0112372$. In our work, $\delta^{13}\text{C}$ of the CO_2 injections were calculated using pulses of standard CO_2 gas that had been indirectly

calibrated to the PDB reference. The contribution of ${}^{17}\text{O}$ to the ${}^{45}\text{CO}_2$ signal was taken into account by the method of Santrock et al. [10]. No outliers were excluded from the reported data.

3. Results and discussion

3.1. Observed effects of quantization error

Fifteen CO_2 injection amounts were used to produce peak areas on the FMAT 252 that varied over 2.5 orders of magnitude. The peaks showed excellent symmetry and narrow peak widths, with a full width at half maximum of <3 s. The mean reproducibility of the area for each injection size, as measured by the area of the $m/z = 44$ signal, was R.S.D. = 13%. Plots of $\delta^{13}\text{C}_{\text{pdb}}$ versus injection size, shown in Fig. 3, are displayed for both the curve-fitting (a) and individual summation (b) methods. The plots are similar in appearance to those presented by others [11] investigating the performance of GC–CIRMS at low signal levels.

In agreement with our previous work [4], we observe modest improvement of precision at low signal levels using the curve-fitting method. Using the summation method, precision deteriorates (S.D. > 1.0‰) for injection sizes less than 400 pmol on column (~50 pmol to the IRMS). Curve-fitting improves this limit to 175 pmol on column (~20 pmol to the IRMS). The integration methods performed comparably and acceptably at large injection sizes. For on-column injections of at least 6.8 nmol (~800 pmol to the IRMS), the individual summation method had a precision of S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) = 0.1‰. The curve-fitting method gave slightly worse precision for large injections, S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) = 0.2‰. It is not obvious why the summation method out-performs the curve-fitting method for very large sample sizes. One possibility is that the precision of the curve-fitting method is limited by differences between the shape of the model EMG function and the shape of real, chromatographic peaks. In this case, increasing the injection size past a certain point would not improve the fit, even though S/N is increasing. Using a different function to describe the peaks may further improve results.

To assess the tolerance of the two integration methods to quantization noise, we evaluated simulated

Fig. 3. $\delta^{13}\text{C}_{\text{pdb}}$ vs. CO_2 injected on column for (a) curve-fitting and (b) individual summation algorithms. Data was collected using a homebuilt system at 24 bits from FMAT252.

12, 14, and 16-bit raw data sets generated from the raw 24-bit FMAT252 data, and processed both by curve-fitting and summation. The accuracy of successive injections was very good, even in the presence of bit noise. For each method, the mean $\delta^{13}\text{C}$ for any two injection sizes did not differ significantly. Plots of $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}})$ versus CO_2 injected on column at all bit resolutions are shown in Fig. 4. Each plot appears to extend asymptotically along the x - and y -axes, and we can evaluate the dependence of precision on quantization error visually; poor performance is indicated by the asymptotic plot moving up and away from the axes. At 24-bit resolution, plots of the summation and curve-fitting methods nearly overlap, except at very small injection amounts, indicating that performance is similar. With increasing quantization error, the minimum amount of CO_2 necessary to reach a given level of precision increases rapidly for the summation method. Curve-fitting is more forgiving; precision from 14- and 16-bit data is comparable to

the 24-bit data. The plot for 12-bit resolution shows some loss of precision, but does not fare as badly as the summation method.

To evaluate the methods objectively, we defined $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}}) = 0.3, 0.6$ and 1.0‰ as benchmarks for high precision. The data were least-squares fitted to a power function, of the form:

$$\text{S.D.} = A[\text{CO}_2]^B \quad (4)$$

where $[\text{CO}_2]$ is the moles of CO_2 injected on column, S.D. is the observed precision, and A and B are constants. The power function was chosen for empirical reasons, because it modeled the observed data acceptably, and the fitted curves can then be compared. The best-fit lines for both the summation (dashed) and curve-fitting (solid) methods are shown in Fig. 4. From the best-fit equations, we calculated the amount of CO_2 injected on-column necessary to achieve the 0.3, 0.6, and 1.0‰ benchmarks (Fig. 5). With least quantization error (24-bit resolution), the

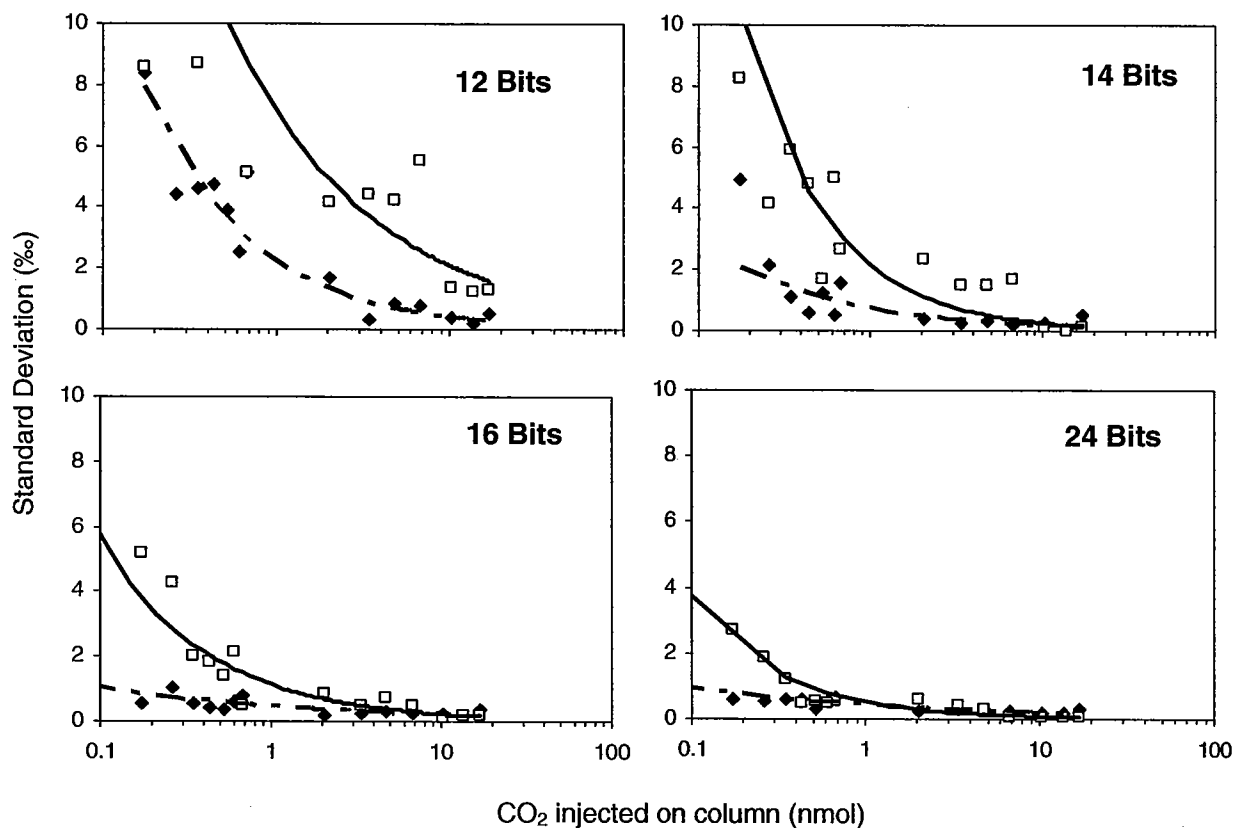

Fig. 4. S.D. ($\delta^{13}C_{pdb}$) vs. CO_2 injected on column at 12-, 14-, 16-, and 24-bit resolutions, calculated by summation (\square) or curve-fitting (\blacklozenge) algorithms. Each point represents four or five replicates. The data for each method and each resolution was fit to a power equation (general form: $S.D. = A[CO_2]^B$, and the best-fit lines are drawn for both methods (solid line: summation; dashed line: curve-fitting).

Fig. 5. Carbon required on-column, in nanomoles, to reach a specified level of precision for a given ADC board resolution. Results are shown for data reduced by curve-fitting and summation algorithms.

summation method requires slightly less CO₂ than the curve-fitting method at the 0.3‰ benchmark (1.86 nmol versus 3.19 nmol). At 16-bit resolution, the summation method requires 6.83 nmol, an increase of 267%, compared to a 25% increase for curve-fitting over the same interval. To reach the 0.6‰ benchmark at 16 bits, summation requires an increase of 224% (from 0.77 to 2.50 nmol), compared to 33% for curve-fitting. At 12-bit resolution, the amount of CO₂ on column necessary to achieve S.D. = 0.6‰ by summation is 107 nmol, which far exceeds the capacity of the GC column. Curve-fitting requires only 6 nmol to reach S.D. = 0.6‰ at 12-bit resolution. As was discussed previously, curve-fitting is superior to summation at the 1.0‰ benchmark, even in the absence of quantization noise. At 24 bits, curve-fitting requires 80 pmol to achieve S.D. = 1.0‰, five-fold less than summation; a similar level of improvement in precision is seen at 14- and 16-bit resolution.

To summarize, in the absence of quantization noise, similar amounts of CO₂ are necessary to achieve precision of 0.3–0.6‰ for both integration methods. The summation method requires a dramatic increase in the injection size to maintain this level of precision in the presence of quantization noise, while the curve-fitting method is relatively unaffected. At a lower standard of precision (S.D. = 1.0‰), curve-fitting is superior regardless of the magnitude of quantization error.

3.2. Theoretical limits of quantization error on precision

In IRMS, the signal is recorded as a voltage proportional to the ion current, and can be reported in amperes or in volts. If the signal is reported in volts, the area of the $m/z = 44$ signal, A_{44} , is related to the moles of ⁴⁴CO₂ that enters the IRMS, [⁴⁴CO₂], by the equation:

$$A_{44} = [^{44}\text{CO}_2] \frac{N_a e}{E} R_\Omega \quad (5)$$

where N_a is Avogadro's number, e is the fundamental charge, E is the absolute sensitivity of the IRMS in molecules/ion, and R_Ω is the feedback resistance of the amplifier.

In the summation method, the background is defined by drawing a line between two background points, (t_1, y_1) and (t_2, y_2); the background area, A , is the

trapezoidal region between this line and the time axis. We can calculate this area by the equation:

$$A(\text{background}) = \frac{1}{2} W(y_1 + y_2), \quad (6)$$

where $W = t_2 - t_1$

Quantization noise is uniformly distributed over an interval and the error for a single measurement is:

$$\sigma_y = \frac{\Delta}{\sqrt{12}} \quad (7)$$

where Δ is the minimum step size of the acquisition boards. A full derivation of this can be found in Haykin's text on digital communication [12]. Assuming that quantization error at y_1 and y_2 is uncorrelated, we can use standard techniques for propagation of errors to determine the total quantization error in measuring the background area, σ_A :

$$\sigma_A = \frac{W\Delta}{2\sqrt{6}} \quad (8)$$

It has been noted that evaluating the effect of chemical noise on precision of isotope ratios is difficult, because this noise is usually highly correlated between the major and minor traces [11]. Unlike chemical noise, quantization noise on each trace should be uncorrelated. This greatly simplifies calculation of the propagation of errors for the relation of the observed isotope ratio, ⁴⁵ R_{obs} , to the actual isotope ratio, ⁴⁵ R_{act} :

$$^{45}R_{\text{obs}} = \frac{A_{45} \pm \sigma_{45}}{A_{44} \pm \sigma_{44}} = ^{45}R_{\text{act}} \pm \sigma_{\text{obs}} \quad (9)$$

where

$$\sigma_{\text{obs}} = ^{45}R_{\text{act}} \sqrt{\left(\frac{\sigma_{45}}{A_{45}}\right)^2 + \left(\frac{\sigma_{44}}{A_{44}}\right)^2} \quad (10)$$

The standard error can be rearranged and expressed in terms of parts per thousand:

$$\begin{aligned} \sigma_{\text{ppt}} &= 1000 \times \frac{\sigma_{\text{obs}}}{^{45}R_{\text{act}}} \\ &= 1000 \times \sqrt{\left(\frac{\sigma_{45}}{A_{45}}\right)^2 + \left(\frac{\sigma_{44}}{A_{44}}\right)^2} \end{aligned} \quad (11)$$

At natural abundance, $A_{45} \sim 0.011A_{44}$. Assuming the feedback resistance is 100× larger for the 45 cup than for the 44 cup, $\Delta_{45} = 0.01\Delta_{44}$. Combining this and Eqs. (5), (8) and (11), we arrive at:

$$\sigma_{\text{ppt}} = \frac{276W\Delta_{44}E}{[^{44}\text{CO}_2]N_a e R_\Omega} \quad (12)$$

Fig. 6. S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) vs. CO_2 injected on column for simulated 16-bit data. The line indicates the theoretical limit of precision as a function of injection size, as calculated from Eq. (12).

At natural abundance, a standard deviation of $\sigma_{\text{ppt}} = 1.0$ is approximately equivalent to $\text{S.D.}(\delta^{13}\text{C}_{\text{pdb}}) = 1.0\%$. We used Eq. (12) to predict the standard deviation as a function of injection size at 16-bit resolution, compensating for an open split ratio of 8.4:1. The integration window, W , was assumed to be constant at 10 s, $E = 5000$, and $R_{\Omega} = 3 \times 10^8 \Omega$. A plot of the calculated limits compared to the observed precision at 16 bits is shown in Fig. 6. There is good agreement between theory and experiment. The calculated precision is within a factor of five of the observed precision for all injection sizes. More striking, the calculated precision is a “lower limit”, as nearly all the measured precisions lie above the theoretical prediction. The biggest discrepancies occur for large injection sizes, where the effect of quantization error is minimized, and other sources of error (e.g. contaminants) may dominate.

Eq. (12) can also be used to demonstrate that quantization error should be negligible for signals acquired with 24-bit digitizers. Eq. (12) predicts that only 0.6 pmol of CO_2 to the IRMS should be necessary to achieve a precision of 0.5% if quantization error is the only limiting factor. However, counting statistics dictate that a minimum number of ions must be formed to achieve a specified precision to overcome the shot-noise limit. Merritt and Hayes [11] give this equation as:

$$\sigma_{\delta}^2 = \frac{(2 \times 10^6)(1 + R)^2}{EmN_a R} \quad (13)$$

where σ_{δ} is the shot noise limited standard deviation, R is the natural abundance isotope ratio, E is the ionization efficiency, m is the moles of CO_2 , and N_a is Avogadro's number. Substituting $E = 5000$ and $R = 0.011$, we find that 6 pmol of analyte is required to achieve $\text{S.D.} < 0.5\%$. Therefore, when high precision 24-bit boards are used, the effect of quantization error is superseded by shot noise.

Our theoretical treatment gives insight into why curve-fitting is less sensitive to quantization error than summation. In the summation methods we have discussed, imprecision in a single data point chosen as the background is multiplied throughout the background correction; for a peak width of N data points, the total quantization error scales as N . In contrast, the algorithms used in curve-fitting minimize the sum of squares between the fit curve and every data point. In curve-fitting, the quantization noise for each individual point is averaged over the entire curve; for N data points, the total quantization error scales as $N^{1/2}$. For a peak width of 10 s and a sampling rate of 10 Hz, this translates into a 10-fold reduction of quantization error.

The theoretical treatment we describe is appropriate for understanding the effects of quantization error on summation integration methods that choose single points on either side of the peak to define a background. It does not examine the limits of other classes of data reduction methods. An obvious improvement to the summation integration method would be to average n points on either side of the peak, which would increase the effective number of bits of

Fig. 7. $\delta^{13}\text{C}_{\text{pdb}}$ vs. CO_2 injected on column for (a) individual summation and (b) curve-fitting algorithms. Data was collected at 16 bits and 10 Hz on the APP2003.

the background measurement by $n^{1/2}$. While this approach could work well for isothermal runs with constant background, it is much less suitable for complex GC–CIRMS chromatograms, where it is not obvious *which* points should be averaged; that is, which points represent pure background and do not contain chemical noise or the tail ends of peaks. Ricci et al., observed that the averaging method gives slightly higher background values than other corrections [3]. They also reported that the dynamic background correction (which uses single points) yielded improved δ -values over the averaging method. Thus, a method may be insensitive to quantization error, but may still give worse results due to other variables.

3.3. Improving precision on a 16-bit IRMS

To test the effectiveness of curve-fitting on GC–CIRMS data acquired by low precision digitiz-

ers, we ran multiple CO_2 injections on an APP2003 using 16-bit digitizers, and otherwise in similar fashion to the work on the FMAT252. A plot of $\delta^{13}\text{C}_{\text{pdb}}$ versus injection size is shown for summation (Fig. 7a) and curve-fitting (Fig. 7b). Fig. 8 shows a plot of S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) as a function of injection size for both integration methods. The theoretical limit on the summation method, calculated from Eq. (12), is shown in the same figure as a dashed line. The observed precision for the summation method agrees well with theoretical predictions; most of the data points lie just above the lower limit curve. Almost 15 nmol of CO_2 on column are necessary to achieve a precision of $<0.3\%$ using the summation method. Using curve-fitting, only 0.76 nmol are necessary to reach that level of precision, a 20-fold improvement. This is greater than the two-fold advantage seen by curve-fitting the 16-bit data from the FMAT 252. One possible explanation is that the APP2003 data is

Fig. 8. S.D. ($\delta^{13}\text{C}_{\text{pdb}}$) vs. CO_2 injected on column for runs on APP2003 with 16-bit boards. The dashed line indicates the theoretical limit of quantization error on precision as a function of injection size, as calculated from Eq. (12).

affected primarily by bit noise, while the FMAT252 data has other sources of noise that cannot be eliminated by curve-fitting. The FMAT252 accepts a three-fold higher flow rate than the APP2003, so there is likely more chemical noise in the FMAT252 signal.

The relative immunity to quantization error with curve-fitting permits the IRMS to be run at lower inlet flow rates, which effectively increases quantization noise by decreasing the number of steps between background and peak with relatively little influence on chemical noise. The advantages of lower inlet flow rates are a longer lifetime for the filament, and reduced need for pumps and pumping capacity. These benefits, plus the reduced need for expensive ADC boards, should make high-precision GC–CIRMS more amenable to portable and low-cost applications. In principle, statistical considerations define the lower limits of flow rates. However, counting statistics dictate that S.D. = 0.5‰ requires 6 pmol of CO₂ to the source for a typical continuous flow IRMS ($E = 5000$), and GC–CIRMS applications usually work well above this limit. Thus, modestly lower resolution and inlet flow rates should not significantly affect performance, so long as appropriate integration techniques are used.

4. Conclusions

Data reduction using curve-fitting is more robust than the conventional summation method in the presence of even modest levels of quantization error. Using data obtained on high precision digitizers, the curve-fitting algorithm required several-fold less CO₂ to reach benchmarks of high precision (S.D. = 0.3, 0.6, and 1.0‰) at any of the three simulated board depths (12, 14, or 16 bits). The poor performance of the summation algorithm was particularly noticeable at the 12-bit resolution, where S.D. < 1.0‰ could not be reached even at the maximum injection size allowed by the dynamic range of the Faraday cups. We

have derived an expression that describes the influence of quantization noise on isotope ratios calculated from raw IRMS data, and shown that it accurately predicts the lower limit of precision. Our theoretical treatment assumes that quantization error is uncorrelated between the $m/z = 44$ and 45 signals, and is appropriate for any data reduction algorithm that uses single points on either side of the peak to describe the background.

Curve-fitting substantially improved precision on GC–CIRMS data collected by an instrument with 16-bit digitizers. The summation algorithm required 15 nmol of CO₂ on-column to achieve a precision of S.D. = 0.3‰, while curve-fitting required only 0.76 nmol. Thus, IRMS with 16-bit ADC boards achieved high precision for less than 1 nmol of C on column, a common benchmark for GC–CIRMS applications, despite using 16-bit ADC boards. Lower inlet flow rates, enabling reduced pumping requirements, may be an important advantage in some applications.

Analytical improvements in irm-GC/MS analyses: Advanced techniques in tube furnace design and sample preparation

LEROY ELLIS* and ANN L. FINCANNON

ARCO Exploration and Production Technology, 2300 W. Plano Parkway, Plano, TX 75075, U.S.A.

Abstract—Peak resolution is an essential requirement for achieving accurate irm-GC/MS compound-specific isotope measurements. Obtaining accurate isotope data from petroleum extracts, in particular, has proven especially difficult due to co-elutions that typically comprise crude oil mixtures. New enhancements in peak resolution in irm-GC/MS analyses have been achieved by substituting a polyimide-coated glass capillary as the furnace reactor. The advantages of the design are significant, and include: (1) incorporation of a zero dead-volume combustion reactor, resulting in almost no loss in gas chromatographic peak resolution, equating to less compound interferences and more accurately measured isotope values and (2) use of direct capillary-to-capillary leak tight, zero dead-volume connections that reduce the incidence of leak problems generally encountered as a result of using fittings of substantially different sizes. In addition, improvements in analytical chromatography using size-exclusion techniques such as urea adduction and molecular sieving reduces the number of components in a sample, and have resulted in the acquisition of more accurate isotope data. Experiments comparing paraffin isotope measurements for whole oil samples to those of urea adducted samples of the same oil have shown that differences of 2‰ are not uncommon. Data from experiments with isotope standards indicate that urea adduction and molecular sieving techniques have no observable fractionation effect on the measurement of isotope values for paraffin components in these mixtures. Considering the intensive effort and expense in generating irm-GC/MS data, the use of relatively inexpensive chromatography techniques such as urea adduction and molecular sieving in isolating components of interest for accurate isotope analysis is justified. © 1998 Elsevier Science Ltd. Key words—Isotope, irm-GC/MS, combustion, petroleum, urea adduction, molecular sieving

INTRODUCTION

Isotope geoscience has established itself firmly as an integral component of applied research, development and resource exploration throughout the world. Information derived from isotope measurements of both inorganic and organic sample components offers unique insights into dynamic geologic and biogeochemical processes occurring in past and present day terrestrial, aquatic, atmospheric and subsurface environments. Particularly for petroleum geoscience, the advent of high resolution gas chromatographic techniques has opened the way for detailed analysis of individual components in complex hydrocarbon mixtures (Sofer *et al.*, 1991). Development of high resolution gas chromatography instrumentation used in tandem with isotope ratio mass spectrometers now permits the accurate measurement of carbon, oxygen, sulfur and nitrogen isotopes on individual sample components (Matthews and Hayes, 1978; Hayes *et al.*, 1990; Brenna, 1994; Merritt and Hayes, 1994; Wong *et al.*, 1995). Future analytical refinements of isotope ratio monitoring-gas chromatography mass spectrometry (irm-GC/MS) are directed towards

further improvements in compound separation and analysis on chromatographic columns used in gas chromatographs, and also advanced sample preparation techniques (Meier-Augenstein, 1997).

Even with the significant advances in compound separation and resolution made possible by the application of high-resolution gas chromatography, it is not expected that complete separation of complex mixtures comprising hundreds to thousands of compounds will be achieved in the short term. While in general this may not even be viewed as necessary for routine GC-MS applications, it is of critical importance in relation to obtaining accurate isotope values in irm-GC/MS applications (Meier-Augenstein, 1997). A minor component co-eluting with a compound of interest can have a significant effect on the measured isotope value if their respective carbon isotopes are significantly different (Ricci *et al.*, 1994; Merritt *et al.*, 1994). Application of mathematical deconvolution techniques in data processing by Goodman and Brenna (1994) have successfully enabled accurate isotope determinations on closely eluting chromatographic peaks with valley overlaps as large as 40%, however significant co-elutions in complex mixtures are less likely to be 'isotopically' deconvoluted with any confidence. Incorrect isotope values achieve very little in re-

*To whom correspondence should be addressed.

lation to data interpretations as variability of only 1–2% is enough to alter and/or invalidate outcomes for many petroleum geochemical applications.

Obtaining simpler, less complex sample fractions through the use of chromatography is, therefore, desired. In measuring *n*-alkane profiles, presently a common application of *irm*-GC/MS petroleum applications, the use of urea adduction and molecular sieve chromatography techniques have proven to be beneficial. Application of either of these techniques results in the adduction and isolation of paraffin fractions containing only *n*-alkanes, monomethyl, one-ring cyclic and in some cases dimethyl alkyl paraffins (Murphy, 1969; Rubinstein and Strausz, 1979; Hoering and Freeman, 1984; Ellis, 1989; West *et al.*, 1990). These simplified paraffin fractions allow for improved accuracy in isotope measurements without interference from co-eluting components or unresolved complex mixtures (UCM) such as those comprising the background matrix.

In this paper, we report on the improvements in component peak resolution obtained from introduction and application of a capillary furnace reactor* in place of conventional tube furnaces (Ellis and Fincannon, 1997). Improvements in isotope data accuracy derived from enhanced peak resolution are also shown in relation to separation of petroleum condensates and a crude oil example. The application of analytical size-exclusion techniques including urea adduction and molecular sieving with respect to potential isotope fractionation issues are also addressed.

EXPERIMENTAL

Samples

The "VGmix" represents a four component mixture of *n*-C₁₀, *n*-C₁₁, *n*-C₁₂ and methyl decanoate reference compounds (ISOCHROM 1-Isotope ratio mass spectrometer user manual, VG Isotech, December 1989). The crude oil saturate fraction used in Fig. 5 is an example of an Indonesian petroleum (95X3797). The condensate used in Fig. 6 to illustrate resolution of gasoline range components was obtained from the North Slope, Alaska (86X1802). The light crude oil (96X4289) used in the sample preparation adduction work represented in Fig. 8 is a petroleum (36.7-API), obtained from Indonesia. The paraffin isotope standard mixture used to test potential fractionation effects of urea adduction sample preparation comprised a synthetic mixture of C₁₂–C₃₀ *n*-alkanes.

*Note added in proof. Since this paper was accepted for publication, a report has been made of the use of a capillary furnace tube for *irm*-GC/MS applications, cf. Goodman K. J. (1998) *Analytical Chemistry* 70: 833–837.

Urea adduction and molecular sieving

The paraffin isotope standard mixture and the whole oil saturate fraction (96X4289) were urea adducted at Baseline Resolution (Plano, TX) to isolate the paraffins (Murphy, 1969). In brief, urea adduction involves application of a saturated solution of urea in methanol to an isolated petroleum saturate fraction dissolved in a toluene-methanol solvent mixture. The urea mixture is allowed to stand overnight for complete adduction, after which, the solvent is pipetted from the urea precipitate. With small sample loadings, a solvent rinse is used to ensure complete recovery of the non-adducted fraction. The urea clathrate in the form of crystals is dried under nitrogen, then the adducted *n*-alkanes, monomethyl alkanes and monocyclic alkanes are recovered with the addition of pentane or hexane after dissolution of the clathrate in water. Similarly, the nonadducted branched/cyclic saturate fraction is also recovered by drying the methanol/toluene solvent under nitrogen, dissolving any residual precipitated urea in water and then adding pentane or hexane.

Molecular sieving analyses were performed at the Houston Advanced Research Laboratories (HARC, Houston, TX). The proprietary HARC technique, referred to as the "PINS" procedure, separates paraffins, monomethyl and monocyclic alkanes and isoprenoids from other saturate compounds (Nolte, 1991). Molecular sieving was also performed at the Australian Geological Survey Organisation (Canberra, ACT) using column chromatography techniques and silicahite molecular sieves.

irm-GC/MS analyses

A Hewlett Packard 5890 gas chromatograph equipped with a model 7673 automatic cool on-column injector system is used in tandem with a Model SIRA II (MicroMass, U.K.) isotope ratio monitoring mass spectrometer. A fused silica column of 60 m × 0.25 mm ID coated with a DB-1 stationary phase (J&W Scientific) was used for analyses of the *n*-alkane standards. Helium was used as carrier gas at a linear gas velocity of 33 cm s⁻¹. For VGmix runs, the GC oven was programmed from 100°C (5 min hold time) to 180°C at 5°C min⁻¹. For condensate runs the GC oven was programmed from 30°C (5 min hold time) to 30°C at 3°C min⁻¹, then from 30 to 310°C (20 min hold time) at 10°C min⁻¹. For saturate fraction runs, the GC oven was programmed from 100°C (0 min hold time) to 310°C at 5°C min⁻¹ (9 min hold time). The combustion furnace was maintained at 900°C during all analyses. Typical MS operating conditions were: ionization energy 100 eV, trap current 600 μA, accelerating voltage 2550 kV. CSIA analyses on the whole oil saturate, molecular sieve and urea adduct fraction reported in Table 4 were

RESULTS AND DISCUSSION

irm-GC/MS system overview

Typical irm-GC/MS systems used in the measurement of organic isotopes are generally comprised of a polyimide-coated glass capillary column in a gas chromatograph, a combustion reactor (sometimes referred to as a "furnace"), a water removal system, an open split, an isotope ratio mass spectrometer and a data processing unit (Fig. 1). In brief, a sample of a particular GC amenable mixture is injected into the column, where the sample components then interact with the column phase material and are chromatographically separated. At the same time, the column is also heated (e.g. to approximately 300°C) to "distill" and volatilize the various components of the mixture according to their respective boiling points. As the components are vaporized, they are transported via helium carrier gas from the capillary column into the combustion reactor or furnace, where the temperature is approximately 900°C. At this elevated temperature and in the presence of a single combination metal oxide catalyst (e.g. copper, nickel and/or platinum), these volatile organic components "react" with the metal oxide and are converted/oxidized to carbon dioxide and water combustion products. Since the metal oxide has only a limited amount of available "bound-oxygen", the catalyst needs to be frequently "regenerated" either *in situ* or as a separate activation process (Merritt *et al.*, 1995). Initial redirection of the sample flow to a vent/FID during elution of sample solvent is performed to eliminate contamination/overloading of the furnace oxidant. Water is removed from the sample stream via the water separator (Merritt *et al.*, 1995). Excess carbon

dioxide formed during combustion, which might otherwise overload the detector electronics of the mass spectrometer is removed through an open split prior to sample entry into the mass spectrometer. The open split maintains a constant pressure, thereby removing any pressure fluctuations that could damage the source electronics. The mass spectrometer subsequently detects and measures separately each respective carbon dioxide isotope as that gas flows through and generates a representative signal. The respective signals are then processed to produce a chromatographic trace illustrating a curve with "peaks" which are representative of the respective carbon dioxide isotopes in the sample. These measurements are further processed to generate numerical data (e.g. the area under the peaks are integrated) which, in turn, are then interpreted in accordance with known relationships to standards in order to arrive at an "isotope measurement" representative of the sample component.

For reliable isotope values, peak integrity is required as the sample components are transported via the carrier gas through to the mass spectrometer. Unfortunately, the need for a combustion furnace, a water removal system and an open split in irm-GC/MS systems introduce a myriad of potential problems related to an increased number of tubing connections. This is especially true for the furnace interface, which typically uses a larger bore glass or ceramic furnace tube connected to capillary lines. Besides the obvious "leak" problems associated with connecting tubing of different internal and external dimensions, all these problems have the added potential of suffering from "dead-volume" and peak separation and resolution is often severely compromised as a result. Dead-volume can be defined as any point in the carrier gas flowpath where the volume in the path increases, e.g. at tubing connections along the flow-

Fig. 2. Comparison of combustion interfaces comparing commercially available glass and ceramic furnace designs with that of the capillary furnace design.

path, etc. As the sample encounters dead-volume along the flowpath, the back pressure on the sample decreases and flow slows as the carrier gas and sample expand and dissipate into the additional space available. With irm-GC/MS systems of the type used to measure hydrocarbon isotopes, dead-volume can typically present problems in the carrier gas flowpath as it passes into the combustion reactor or furnace from the GC.

Tube furnace design

Furnaces used in irm-GC/MS systems contain a metal oxide catalyst (copper, nickel and/or platinum) in pelletized or extruded wire form, and generally use a larger diameter glass or ceramic tube (e.g. 0.6 mm ID) to form the sample flowpath [Fig. 2(a)]. This relatively large diameter tube is connected directly to the smaller capillary GC column (e.g. approximately 0.25 mm ID). The connection of the larger tube in the furnace to the capillary tube of the GC column can often result in the creation of significant dead-volumes. Dead-volumes have the potential to severely affect the final results of the carbon dioxide isotope measurements, and can create broader peaks with "peak

tailoring" on the chromatographic trace. Maintaining leak-free connections with this type of system furnace configuration is problematic. Accordingly, improvements are needed in the sample flowpath to eliminate dead-volume, and thereby maintain peak integrity of sample components after they leave the chromatographic column.

Replacement of standard glass or ceramic tube furnaces with a capillary combustion tube furnace [Fig. 2(b)], has been shown to be extremely effective in maintaining peak resolution through a smaller and more leak resistant system. Any dead-volume attributable to the increased diameter of the previous furnace tube designs is also substantially eliminated. Minimizing peak broadening effects caused by perturbed gas flow through larger internal volume furnace reactors was achieved by substituting a polyimide-coated fused silica capillary as the furnace reactor. Preferably, a length of deactivated polyimide-coated fused silica capillary tube having basically the same ID as that of the GC capillary column (between 0.22 and 0.33 mm) is used in forming the combustion tube. In addition, as the polyimide-coating of the capillary column is unstable at the elevated temperatures (i.e. 900°C)

| Capillary | 0.022 | 0.011 | 89 |
| Wire | 0.01 | 0.002 | N/A |

^aGlass and ceramic combustion tubes were purchased as 0.5 mm ID tubes; however scanning electron microscope measurements revealed actual tube dimensions to be of the order 0.65 mm ID [Fig. 3(b)]. ^bCalculated combustion tube volumes based on a reference 30 cm length. N/A means not applicable.

within the furnace, the polyimide-coating is removed from the tube along that portion of its length which will actually lie within the furnace, thus leaving an uncoated section of fused silica. Length(s) of catalytic wire (e.g. copper, nickel and/or platinum) are inserted into the capillary combustion tube and are sized to extend through that portion of tube situated within the furnace. Since the uncoated fused-silica capillary is potentially fragile, the capillary tube containing the metal oxide catalyst wires is placed within a glass or ceramic tube sheath for support. Direct capillary-to-capillary connections are then made using standard low or zero dead-volume capillary fittings, both to the column exiting the gas chromatograph, and, to the capillary column leading from the furnace to the isotope ratio mass-spectrometer via the water trap and open split.

The advantages of the capillary isotope furnace design are numerous. Firstly, the reduced volume of the capillary furnace reactor relative to existing commercial furnace reactors using larger bore glass or ceramic columns (Fig. 3), results in almost no loss in peak resolution to that obtained on compound separation upon exiting the gas chromatograph (Lambert *et al.*, 1984). Table 1 lists the internal diameters of standard glass and ceramic furnace tubes along with the internal area volumes related to an arbitrarily selected furnace tube of 30 cm length. The table also lists the internal area volumes associated with tube furnaces constructed from GC deactivated capillary tubing of 0.22, 0.25, 0.32 and 0.53 mm ID. The internal area volume taken up by standard metal oxide combustion wires is also noted for reference purposes. Using commercially obtained glass/ceramic furnace tube internal diameters as a reference (i.e. these represent the smallest commercially available furnace reactors), the percentage reduction in area volume associated with the use of progressively smaller furnace tube alternatives is shown. For example, the 0.53 mm ID capillary furnace tube represents a 34% volume reduction, while the 0.22 mm ID capillary furnace tube represents an 89% volume reduction over standard glass and ceramic furnace tubes. Clearly, significant improvements in area volume reduction can

be achieved through construction of a capillary tube furnace relative to standard glass and ceramic tube furnaces. Although the metal oxide combustion wires only occupy 0.002 cm³ of space each, our experience has indicated that only one wire should be used for the 0.22 or 0.25 mm ID constructed capillary tube furnaces, two wires for 0.32 mm ID constructed tube furnaces and three wires for 0.53 mm ID constructed tube furnaces. Use of more wires than suggested above appeared to result in a greater tendency for breakages in the uncoated glass capillary due to a "corkscrewing" effect the metal oxide wires adopted when routine maintenance required cooling of the furnace oven. Increases in column head pressure were also noted when additional wires were inserted, perhaps attributed to column obstructions resulting in back-pressure (Lambert *et al.*, 1984).

By far, the greatest improvement in the chromatography observed, resulted from the use of direct capillary-to-capillary zero dead-volume connections. The advantage of direct capillary-to-capillary connections, equates to fewer problems associated with gas leaks, caused by using fittings of substantially different sizes, as it permits the operator to use standard well proven leak tight capillary gas fittings. By providing a continuous capillary flow-path through the irm-GCMS unit, substantial amounts of dead-volume are eliminated, thereby increasing the peak resolution and enabling better recognition of peak start and peak end positions needed to accurately measure component isotope responses. The capillary columns themselves are cheap and standard to that obtainable from most laboratory equipment suppliers. The technique for constructing a capillary furnace reactor is simple and uses commonly available gas chromatographic materials.

Figure 4 shows three *m/z* 44 chromatograms of a reference mixture (VGmix, see experimental) provided by the instrument manufacturer that allows for comparisons in chromatography between standard tube furnace designs and the newly employed capillary tube furnace. Figure 4(a) shows a *m/z* 44 chromatogram of the VGmix analyzed under the instrument manufacturers specifications (chromato-

gram taken from VG reference manual). Figure 4(b) shows a m/z 44 chromatogram of the same VGmix analyzed "in-house" using a standard ceramic tube furnace. Comparison of Fig. 4(a) and (b) shows almost identical chromatography associated with the VG mix when analyzed under similar instrument conditions. Figure 4(c) shows a m/z 44 chromatogram of the VGmix making use of the modified capillary furnace design, and analyzed under identical run conditions to the chromatogram obtained in Fig. 4(b). Clearly, the introduction of a capillary tube furnace results in significant improvements in compound chromatography and resolution. The compound separation and resolution obtained upon exiting the GC oven is maintained, which greatly improves the determination of the isotope measurements and hence, the accuracy of the data. It is important to note, that seemingly modest improvements in peak resolution will actually result in large degrees of separations between individual components, thus facilitating the analysis and interpretation of complex mixtures such as petroleum fractions with greater confidence and efficacy.

Peak resolution

Peak resolution relating to compound separation and analysis is an essential requirement to achieve accurate compound specific isotope measurements (Meier-Augenstein, 1997). Effluent from a gas chromatograph capillary column connected to a glass or ceramic furnace tube will typically encounter a region of a substantially larger internal volume relative to the capillary column, resulting in peak broadening. Higher gas chromatograph head pressures creating faster column gas flows can result in narrower peak profiles (Lee *et al.*, 1984). However, this does not solve the fundamental problems related to peak resolution and compound separation, and any peak broadening effect or component co-elution caused by flow through a larger internal volume glass or ceramic tube furnace is permanent. The "sharper" and better resolved the peak on a chromatographic trace, the more accurate is the measurement of that particular carbon dioxide isotope signature (i.e. integrated area under the peak) since the exact points along the curve on the chromatographic trace at which a particular peak begins and ends (i.e. the points between which the curve is

Table 2. Comparison of measured isotope values obtained for a set of *n*-paraffin standards before and after treatment with urea clathration techniques

to be integrated) can be more readily identified. Also, in more complex mixtures where two or more peaks elute close together, the "slower" and isotopically lighter component of one may be erroneously included in the data of the following peak (Hayes *et al.*, 1990). While these errors may appear to be small with respect to peak area, they nevertheless generate significant errors in the precise isotope calculations ultimately made from these measurements.

Examination of the literature reveals large variations in the resolution of *n*-alkane *m/z* 44 selected ion chromatograms of petroleum samples, as performed on different instruments in various laboratories (irm-GC/MS analysis is typically performed on saturate fractions of crude oil mixtures when paraffin isotope data are required for geochemical interpretations). Figure 5 shows a *m/z* 44 chromatogram of a urea adducted saturate fraction obtained from a crude oil mixture. It can be observed in Fig. 5 that excellent baseline resolution of the *n*-alkanes is obtained from the capillary combustion furnace. Resolution of components eluting between homologous *n*-alkanes, that include monomethyl and cycloalkane components can clearly be seen (see inset) and in some cases are also baseline resolved relative to other minor "interfering" components.

Other recent petroleum applications of irm-GC/MS relate to analysis of low molecular weight gasoline range (C₄-C₁₀) components (Bjorøy *et al.*, 1994). Figure 6 shows a *m/z* 44 selected ion chromatogram of C₄ to C₇ component resolution obtained from analysis of a petroleum condensate. As with Fig. 5, excellent baseline separation of many of the gasoline range components is obtained through use of a capillary furnace and compound resolution is directly comparable to that obtained from standard high resolution GC analysis.

Size-exclusion techniques

In order to assess the viability of chromatography techniques such as urea adduction and molecular sieve separations for irm-GC/MS applications, the question of introduced isotopic fractionation must

first be addressed. While, in general, no isotopic fractionation of *n*-alkanes isolated using urea adduction has been reported in the literature, there exists little isotope data in relation to the lower molecular weight series (<C₂₀) of *n*-alkanes that are not quantitatively adducted. To investigate this issue, a standard mixture of commercially available C₁₂-C₂₆ *n*-alkanes was prepared and urea adduction sample preparation applied.

Figure 7 shows *m/z* 44 chromatograms for the standard paraffin mixture [Fig. 7(a)], together with the same mixture after urea adduction [Fig. 7(b)]. Investigations in this work found that the technique of urea adduction fails to completely adduct *n*-alkane compounds with less than 20 carbons. This introduces compound fractionation and therefore also the possibility of isotope fractionation. Table 2 lists the background subtracted measured isotope values for the standard paraffin mixture and also the measured isotope values for the standard paraffin components after urea adduction. From these data, it is clear that no isotope fractionation of the paraffin components in the standard mixture, including those that were only partially adducted (e.g. C₁₂, C₁₆ and C₁₉), has occurred. Reproducibility of the measured isotopes was less than 0.1‰ in all cases. Evidence is presented, therefore confirming that isotopic fractionation was not observed to occur with the use of urea adduction sample preparation techniques in this study.

To examine the effect that other co-eluting components or the background matrix may have on the measurement of individual isotope values for paraffins in a typical crude oil, a comparison of data acquired from irm-GC/MS analysis of a whole crude oil with that of both a urea adducted and molecular sieved sample was undertaken. Figure 8(a) shows a *m/z* 44 chromatogram of a light crude oil analyzed directly or "neat" with no sample preparation. This chromatogram shows a dominant series of *n*-alkanes with a carbon distribution ranging from C₁₁ to C₃₀. The sample, although unaffected by biodegradation or PVT migration/evaporation effects, does show a slightly elevated baseline reflecting an unresolved complex mixture

or "background matrix", that is commonly observed in most crude oils. Figure 8(b) shows a m/z 44 chromatogram of the same light crude oil saturate fraction after treatment with molecular sieves

Similarly to urea adduction, molecular sieving fails to completely adduct paraffin components with less than 20 carbons (Ellis, 1989; West *et al.*, 1990). Figure 8(c) shows a m/z 44 chromatogram of the

Table 3. Comparison of urea and molecular sieving adduction efficiencies for *n*-alkanes in a crude oil

| Compound | Urea (%) | Molecular sieving (%) |
|-----------------------------|----------|-----------------------|

urea adducted saturate fraction of the same light crude oil shown in Fig. 8(a). Table 3 lists the comparative efficiencies for *n*-alkane adduction between the two sample preparation techniques, and shows molecular sieving techniques can be observed to adduct a greater proportion of the paraffin components below *n*-C₂₀ relative to urea sample treatment in this case. Both adduction sample

preparation techniques also isolate monomethyl, one-ring cyclic and in some cases dimethyl alkyl paraffins (Rubinstein and Strausz, 1979; Hoering and Freeman, 1984; Ellis, 1989). One notable chromatographic feature observed in Fig. 8(b) and (c) is the absence of an elevated baseline, suggesting the adduction sample preparation techniques also worked effectively in removing co-eluting components that typically comprise a background matrix/unresolved complex mixture (Killops and Al-Juboori, 1990; Ellis *et al.*, 1994).

Table 4 lists the measured isotope values for the *n*-alkane components in the "neat" oil analysis along with those data obtained from the same *n*-alkane components after saturate fraction isolation via column chromatography and subsequent sample treatment with molecular sieving and urea adduction techniques. Comparison of those data for *n*-alkane components isolated from the molecular sieve and urea adducted sample fractions reveals a

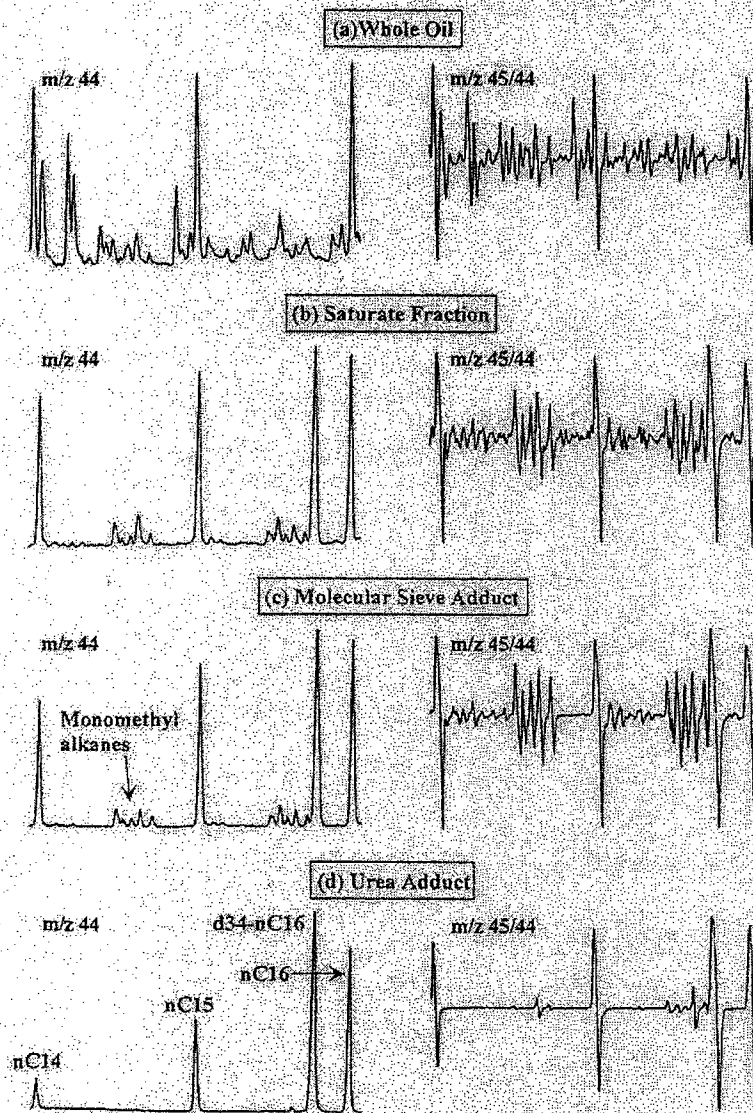

Fig. 9. irm-GC/MS selected ion chromatograms (m/z 44 and m/z 45/44) showing comparison of chromatograms of (a) light crude oil ("neat"), (b) isolated saturate fraction, (c) molecular sieve adducted fraction of saturated components and (d) urea adducted fraction of saturated components.

very close match with all individual sample components except one ($n\text{-C}_{15}$), differing by no more than 0.7‰ between the fractions. The measured isotope value for $n\text{-C}_{15}$ in the urea adduct is clearly anomalous, since measured isotope values for this compound in the corresponding whole oil and saturate fraction analysis correlate well with that of the molecular sieving measured isotope value. The majority of components (9 of 16) however, agreed to within 0.2‰ on average, a value considered well within the instrument precision error. The close agreement of the measured isotope values between

both adduction techniques indicates that molecular sieving, as previously shown with urea adduction (Table 2), shows no measurable isotope fractionation effect.

Isotopic analysis of paraffins in urea and molecular sieve adduct fractions should, therefore, provide analyses less affected by co-elutions problems. Measured isotope values for sample components in these fractions should be of higher overall precision and accuracy as compared to a whole oil analysis of the same sample. Employing measured isotope values for individual n -alkanes in the urea adduct

urea adduct/molecular sieve adduct
 <saturate<whole oil fraction

Techniques used to increase the accuracy of an isotope measurement may include the addition of an internal standard of known isotopic composition (Merritt *et al.*, 1994). Commonly for petroleum applications, a perdeuterated *n*-alkane is preferred, which has the advantage of never co-eluting with an *n*-alkane component of interest and also exhi-

Although crude oil compositions vary considerably from sample to sample, the examples shown here are intended to reflect general features typically observed with most oils, such as a predominance of *n*-alkanes between C_{10} and C_{30} and a low-level background matrix or UCM. These characteristics, are in fact, those usually associated with "good quality" oils, whereas quite often crude oil mixtures may be substantially less "clean" in comparison, due to effects of biodegradation, low maturity and variable source quality. Considering the intensive effort and expense in generating firm GC/MS data, the use of relatively inexpensive chromatography techniques such as urea adduction and molecular sieving in isolating components of interest for accurate isotope analysis would appear to be justified.

Introduction of a capillary tube furnace in place of standard commercially obtained glass ceramic tube furnaces has resulted in significant improve-

ments in chromatographic resolution of complex petroleum mixtures analyzed using irm-GC/MS techniques. Application of urea adduction and molecular sieve sample preparation techniques to complex petroleum mixtures has been shown to provide "simpler" petroleum fractions containing fewer components concomitant with less co-elution problems. No isotope fractionation was observed using the urea adduction and molecular sieve sample preparation techniques. Use of a capillary furnace tube together with application of sample preparation techniques has resulted in significant improvements in both the precision and accuracy of measured isotope values in irm-GC/MS analysis of complex petroleum mixtures.

Acknowledgements—The authors thank ARCO for permission to publish. We would also like to thank Long Liang for his SEM analysis and Albert Holba for internal reviews of the manuscript. Many thanks to Dr R. Summons and J. Hope (AGSO) for analyses and assistance. The authors would also like to acknowledge Drs K. Hall and C. Boreham for reviewing the manuscript and providing many helpful suggestions, which have greatly contributed to improving the quality of this paper.

Review

Isotopic Fractionation of Organic Compounds in Chromatography

Crist N. Filer

I. Introduction

During the past fifty years the development of synthetic methods to prepare and analytical methods to detect isotopically labeled organic compounds has made them exceedingly valuable tools for research. Stable isotopes such as ^2H , ^{13}C and ^{15}N have been used to elucidate biosynthetic schemes and reaction mechanisms, and radioisotopes such as ^3H , ^{14}C , ^{32}P , ^{35}S , and ^{125}I have been exploited to clarify metabolic pathways, facilitate biological assays and deduce the structure of complex molecules like DNA.

After the synthetic preparation of an isotopically substituted organic compound it is a typical practice to corroborate isotopic product identity by performing cochromatography (demonstration of the same R_f or retention time) with an authentic nonlabeled standard in multiple chromatographic systems. This exercise is especially crucial for radioisotopes like tritium where the tiny mass of product involved often precludes alternative identity confirmation such as IR, NMR and the like. It is our experience that for the vast majority of cases such isotopically labeled compounds completely cochromatograph with authentic nonlabeled substances. However, for over forty years, some interesting and well documented examples have emerged for all types of chromatography where isotopically labeled compounds and authentic unlabeled standards simply do not cochromatograph. In fact in some cases dramatic baseline peak resolution can be achieved. This

chromatographic phenomenon has been referred to as isotopic fractionation and was last reviewed by Klein (1) over thirty years ago. In this review the phrase "isotopic fractionation" refers only to chromatographic isotopic fractionation. Since Klein's review a partial discussion of the topic has appeared in several other limited publications (2-5).

The purpose of this discussion will be to review the documented literature instances of chromatographic fractionation for isotopically labeled organic compounds, especially the many intriguing examples that have been published since Klein's first review. It excludes a number of unpublished instances of the phenomenon for compounds confidential to us or those we have collaborated with. This summary was presented in part at a recent Philadelphia International Isotope Society (IIS) meeting (6) and the cited papers usually fall within two categories. Some of them are totally devoted to an observation of isotopic fractionation often convincingly documenting it, exploring its scope, proposing an explanation or mechanism for its occurrence and placing it in context with other examples. However, many cited authors in diverse disciplines often disclose a single well characterized observation of isotopic fractionation as a curious side issue to the main body of their work. It is clear that some of these investigators were unaware of the phenomenon prior to their own observation and sometimes surprised by it. This review most likely captures all of the pertinent references on isotopic fractionation from 1955 to the end of 1997, but has excluded other articles whose observation or claim of the phenomenon was somewhat ambiguous. Articles were located not only by a painstaking and meticulous review of key chromatographic journals (tables of contents and indices) since 1955, but also by exhaustive cross reference checking of retrieved articles and citation searching of past papers to uncover later ones referencing them. The chromatographic techniques covered include gravity column, ion exchange, electrophoresis, paper, thin layer, gas and high pressure liquid chromatography. Although there are several reports of isotopic fractionation for the technique of countercurrent distribution (7-9), this topic will not be addressed here. Finally, the proposed factors causing chromatographic peak separation and its implications will be reviewed. Armed with this information, investigators in many life science areas using labeled

compounds will be better prepared to anticipate and interpret such results if they occur in their own laboratories.

II. Column Chromatography

Perhaps the first mention of isotopic fractionation for an organic compound in the chemical literature was by Van Dyken in the abstracts of a 1955 American Chemical Society meeting in Minneapolis (10) and later in a larger paper where the same data was incorporated and discussed (11). It was observed that on a silica gel column eluted with mixtures of butanol:chloroform, tritium labeled acids like formic acid manifested separation from their unlabeled standards. In most cases the tritiated acid eluted later than the unlabeled analogue as shown by specific activity (the measurement of radioactivity per unit of mass, often expressed as mCi/mmol) determinations of successive peak cuts.

Isotopic fractionation has been observed on column chromatography not only for such small molecules but also for much larger ones like the steroids [acetate-2-³H] cholesterol acetate (12-14), [1,2-³H] aldosterone (15-19), [³H] 7-dehydrocholesterol (20), [1,2,6,7-³H] testosterone (21), a tritiated ecdysone related compound (22) and lipids like [³H] methyl linoleate (23). In many of these examples the coelution of analogues labeled separately with carbon-14 and tritium was examined by measuring the changing ratio of ¹⁴C/³H on successive peak cuts during chromatography. A great deal of effort was expended in ruling out impurities and other chromatographic artifacts as alternative explanations for the observations since many of these early reports were still met with relative disbelief (1). From these early studies several conclusions were already drawn about the phenomenon in the context of column chromatography. Tritium more often than carbon-14 appeared to cause isotopic fractionation and its presence almost always retarded compound elution on silica gel compared to the unlabeled substance. Also, the location of tritium labeling appeared to be a strong factor in the mechanism and extent of isotopic fractionation. Finally, it was appreciated that the degree of isotopic fractionation could be effected by column conditions.

Several examples of isotopic fractionation with stable isotope labeled organic compounds by column chromatography have been reported. A deuterium labeled

prostaglandin showed isotopic fractionation during column chromatography but its oxygen-18 analogue did not and use of the latter circumvented this "undesirable" property (24). Carotenoids labeled with deuterium could be separated from their unlabeled counterparts on activated magnesium oxide (25) and in this instance the deuterated compound migrated more slowly. Finally, several deuterated p-xylenes were separated by column chromatography from unlabeled analogues by cleverly taking advantage of a differential host/guest mechanism with tetrakis(4-methylpyridine)nickel (II) thiocyanate that had previously been employed to separate nonlabeled aromatic isomers (26). This appears to be the first report utilizing such an inclusion process to promote isotopic fractionation, but surprisingly the authors stopped short of suggesting what would seem to be a possible steric explanation (see Section IX).

III. Ion Exchange Chromatography

Although obviously related to column chromatography, ion exchange chromatography is unique enough to merit separate discussion. A very systematic study of isotopic fractionation as influenced by isotope location was the work of Piez and Eagle (27, 28) using ion exchange chromatography on several amino acids labeled with carbon-14. Elution of a Dowex 50 column with a pH gradient clearly demonstrated that several carbon-14 labeled amino acids migrated more slowly on the column than their unlabeled counterparts. It was evident from even this early work that the increased molecular weight of the radiolabeled compound alone could not satisfactorily explain the observed degree of isotopic fractionation, and it was also apparent that the position of the radiolabel in the amino acid had a marked effect on its mobility. In general, the greatest amount of isotopic fractionation was noted when carbon-14 was adjacent to the amine. Since this initial observation, other related instances of carbon-14 amino acid isotopic fractionation by ion exchange chromatography have been reported (29-33), discussing both the mechanism of the phenomenon and its implications. A separation was also described for [^{14}C] formic acid (34) via ion exchange chromatography on a strongly basic Dowex-2 resin. In this latter example the carbon-14 labeled compound was significantly enriched in the earlier eluent.

Several compounds labeled with tritium have been reported to show isotopic fractionation in this medium. [^3H] 2-Aminopurine eluted earlier than authentic unlabeled standard on a Dowex 1-X8 column (35). Special care was taken to exclude impurities as the cause of isotopic fractionation in this instance by paper chromatography analysis of fractions at the front and back of the radioactive peak. It was found that both the early and late eluting peak fractions were homogeneous and cochromatographed with authentic 2-aminopurine. Noting that the degree of isotopic fractionation was influenced by eluent pH, this report was also one of the first to implicate the influential role of tritium in modifying the polarity of an adjacent nitrogen atom. Several reports on the isotopic fractionation of tritium labeled amino acids by ion exchange chromatography have appeared (36, 37). It was observed that unlike carbon-14, which almost always resulted in a less mobile amino acid, the retention time of an amino acid labeled with tritium was very dependent on the radiolabel location. On a Dowex 1-X4 column, several carbohydrates including [$6\text{-}^3\text{H}$] maltose (38) and [$6\text{-}^3\text{H}$] D-glucose also exhibited isotopic fractionation (39). While there was only a slightly increased compound mobility in the former example, in the latter it was significant enough for the authors to speculate that with early fraction collection and recycling, very isotopically pure [$6\text{-}^3\text{H}$] D-glucose could be obtained. Also, the separation of tritium labeled folate derivatives from carbon-14 and unlabeled folate analogues (40) as well as the earlier elution of [^3H] ethylenediamine-ouabain (41) by ion exchange chromatography have been described.

A few reports have related the ion exchange isotopic fractionation of stable isotope containing organic compounds. [^{15}N] Urea was enriched in isotopic content by means of its isotopic fractionation on cation exchange chromatography (42) and several deuterated glucose isomers were separated by anion exchange chromatography (43). In this latter example using two CarboPac PA1 columns in series, baseline separation was realized for [$1\text{-}^2\text{H}$] D-glucose (earlier eluting) and unlabeled D-glucose. Also by this method almost baseline separation was achieved for [$1\text{-}^3\text{H}$] D-glucose (earlier eluting) from [$2\text{-}^3\text{H}$] D-glucose. The authors concluded that these results rule out mass or hydrophobicity as being operative in the separation. Rather, they proposed that the inductive effect of the [$1\text{-}^2\text{H}$] D-glucose

C-²H bond reduces the adjacent C-O bond strength thereby increasing the adjacent O-H bond strength making it less acidic than in the case of the [2-²H] D-glucose.

IV. Electrophoresis

Only a few examples of isotopic fractionation by means of electrophoresis have been described but several have been fairly striking. Giovanelli and coworkers reported the significant isotopic fractionation of [³H] GSH sulfonic acid (44). With regard to stable isotopes, [²H] dansylated methylamine separated with almost baseline resolution as a faster peak from unlabeled compound via micellar electrokinetic capillary chromatography (45, 46). In this study the addition of methanol to the mobile phase, use of long capillaries, high voltages and a stepped application of the voltage were key contributing factors to the successful separation observed.

Recently, Chiari described the complete separation of several deuterated compounds (such as [²H] aniline, [²H] benzoic acid and [²H] pyridine) from unlabeled compounds by capillary zone electrophoresis (47). The mechanism suggested for this fractionation was that the electron donating inductive effect of ring deuterium (compared to hydrogen) altered the ionization constant of nearby functionality. Using this same technology, Terabe and coworkers were also able to completely resolve unlabeled benzoic acid (earliest eluting) from single (middle eluting) and double (last eluting) labeled [¹⁸O] benzoic acid isotopomers (48). The authors optimized applied voltages, capillary tube lengths, buffer pH and electroosmotic velocities to achieve this stunning separation and proposed that this method was more efficient than HPLC to obtain the resolution of such closely related ionizable compounds.

V. Paper Chromatography

To date, instances of isotopic fractionation reported for paper chromatography have been few. Several deuterated amino acids and carbohydrates showed partial separation from authentic standards in this medium (49, 50). In both cases the deuterated compounds migrated more slowly than the unlabeled substances. Other examples include the separation of tritiated steroids

from cold or carbon-14 analogues during paper chromatography as demonstrated by either changing specific activity or $^{14}\text{C}/\text{H}$ peak ratios measured on the chromatograms (51-55). Several of the authors recognized and cautioned that the phenomenon must be taken into account for such studies as isotope dilution analysis of steroid secretion rates.

VI. Thin Layer Chromatography

The technique of thin layer chromatography (TLC) has only a few but certainly some of the most dramatic instances of isotopic fractionation yet observed. Perhaps the very first report of its occurrence on TLC was the example of [^{14}C] sodium formate, separated as a higher R_f spot on a basic silica gel system (56). TLC isotopic fractionation has also been reported for carbon-14 labeled dichlorobenzene isomers (57) as well as [1,2- ^3H] cholesterol (58), [2,4- ^3H] lithocholic acid (59), [^3H] Juvenile Hormone I (60), the calcium antagonist [^3H] VUF-4576 (61) and [^3H] methadone (62). Two studies on the TLC behavior of isotopically substituted analogues of imipramine have been described. Silica gel TLC of [benzene ring, N-methyl- ^3H] imipramine in basic solvent systems such as methanol:ammonia (200:3) caused separation of it as a lower R_f spot from the higher R_f unlabeled imipramine (63). However, isotopic fractionation was not observed in acidic silica gel TLC systems. Also, no isotopic fractionation was observed for [benzene ring- ^3H] imipramine, even in basic TLC systems. A photograph of the actual visualized TLC plates documented the separations observed in this study.

Our interest in tritiated radioligands for receptor binding studies prompted us also to study the TLC isotopic fractionation of [N-methyl- ^3H] imipramine (64). Our results completely paralleled those just described since we too observed pronounced isotopic fractionation between (lower R_f) [N-methyl- ^3H] imipramine and unlabeled imipramine in basic TLC systems but complete cochromatography between them in acidic TLC systems. Also, we saw no isotopic fractionation between [benzene ring- ^3H] imipramine or [N-methyl- ^{14}C] imipramine and unlabeled imipramine in any TLC system. In our case the measurement of TLC isotopic fractionation was exceptionally easy because of the ability after autoradiography to simply overlay the developed film upon the visualized TLC

plate. These results presented compelling evidence that the exclusive cause of isotopic fractionation for these compounds was deuterium or tritium substitution on the N-methyl groups. Therefore, although only a few examples of isotopic fractionation have been reported for TLC, it is important to be aware of its occurrence with the supportive role that this quick and convenient chromatographic method plays in the synthesis and characterization of labeled substances important to the life sciences.

VII. Gas Chromatography

With most of the aforementioned chromatography techniques, our discussion thus far of isotopic fractionation has been dominated by radioisotopes. Gas chromatography (GC) was a method where the property was first observed and widely studied for stable isotopes in general and deuterium in particular. Therefore it is only fitting to cover this isotope first. The subject was reviewed for selected small molecules almost thirty years ago by Van Hook (65).

The very first reported separation of any deuterated compound from its hydrogen analogue by GC would seem to be that of Wilzbach and Riesz (66). On a 4 meter didecyl phthalate column at 53°C with a helium flow rate of 45 mL/min, they were able to observe a partial separation of the earlier eluting perdeuterated cyclohexane from cyclohexane. Other workers using different GC conditions such as glass capillary columns (67), sandwiched capillary columns (68) and porous polymer beads (69) subsequently improved upon this same separation to almost baseline resolution. In these cases also, deuterated cyclohexane eluted faster than cyclohexane. Other reports of this separation (70, 71) as well as further examples of isotopic fractionation for other alkanes labeled with deuterium soon followed. They included 2,3-dimethylbutane (72), butane (73), ethane (74-78), ethylene dibromide (79) and alpha-1,2,3,4,5,6-hexachlorocyclohexane (80). The technique of recycle gas chromatography was exploited to enhance the separation factor in one of these investigations (73). Similar separations of a number of other deuterated alkanes have also been described (81-83). The isotopic fractionation of methane from its deuterated analogues has perhaps received the most attention (69, 73, 75, 77, 84-100). Some of these articles related the excellent separation of CH_4 and C^2H_4 with

the order of elution depending upon the GC conditions used. In one study (94) a marked difference in the separation between these isotopomers as a function of carrier gas on a Porapak S column was observed, and the degree of peak separation effected by each carrier gas was found to be in the order helium > argon > nitrogen > carbon dioxide. In several reports the reasonably clean separation of the four possible deuterated isotopomers of methane was achieved at low temperature. On a glass capillary column, the elution order was CH_4 , CH_3^1H , CH_2^2H_2 , CH^3H_3 and C^4H_4 (88). However, using graphon coated with 0.1% squalane, this elution order was reversed (77).

Besides saturated hydrocarbons, several other classes of deuterated compounds have demonstrated isotopic fractionation. Deuterium labeled olefins such as ethylene (69, 77, 101-112), propylene (101) and 2-butene (105) have been studied. In one of these reports (104) the use of a long silver nitrate-ethylene glycol column allowed nearly baseline separation of deuterated ethylenes differing by only a single deuterium. Additional modes of column complexation were operative in several other of these examples and in one of them (110) the use of a coordination compound, dicarbonylrhodium (1) 3-trifluoroacetylcamphorate, in squalane on a capillary column promoted the essentially complete resolution of all isotopomers of deuterated ethylene. The authors predicted that use of this technique would accomplish the separation of other deuterated olefins and that an enhanced separation could be anticipated for tritiated olefins. Other unsaturated deuterated hydrocarbons have also been found to exhibit isotopic fractionation (113).

Compounds labeled with deuterium such as benzene (69, 114-124), toluene (75, 116, 123-126) and xylenes (127-130) have also been examined. In one of these articles (115) the nature of the GC stationary phase was found to exert a profound effect on the degree of $\text{C}_6\text{H}_6/\text{C}_6^2\text{H}_6$ separation. Capillary columns coated with dinonyl phthalate, squalane and silicone oil afforded increasingly improved separations of the two compounds with perdeuterobenzene most often emerging as the earlier peak. In another study (116) almost complete separation of the isotopic pairs $\text{C}_6\text{H}_6/\text{C}_6^2\text{H}_6$ and $\text{C}_7\text{H}_8/\text{C}_7^2\text{H}_8$ was achieved via an open tubular thick layer graphitized carbon black column. One investigation (123) explored the relative influence that ring and side chain aliphatic deuteration would have in enhancing

peak separation and concluded that side chain labeling had more of an effect. The GC isotopic fractionation of other deuterated aromatics has been described (131, 132), and several reports about the separation of deuterated alkynes have also appeared. For deuterated acetylene (133) the order of elution on a Chromosorb P column was C_2H_4 , C_2H^3H and $C_2^2H_2$. However, for the isotopomers of deuterated 2-butyne the order of elution on a capillary column was reversed with the most deuterated species eluting first (134).

More polar compounds labeled with deuterium have also demonstrated isotopic fractionation on GC. These include acetone (69, 116, 135-141), acetonitrile (77), chloroform (135, 141), ethanol (135-138), methanol (77, 135-137), pyridine (116, 136, 137) and 2-butanol (142). In ref. 141 the use of cyclodextrins as host inclusion compounds for isotopomer separation was reported for the first time. It was demonstrated that not only was the cavity size a major factor in isotopic fractionation but also the cavity environment and cyclodextrin ring substituents were very influential. In the last study (142) the observation of the difference in NMR chemical shifts between deuterated and unlabeled alcohols with the NMR shift reagent $Eu(fod)_3$ inspired the authors to use it in effecting the GC separation. Further examples of GC isotopic fractionation for compounds labeled with deuterium include DMSO (143) and *N*-methylformamide and *N,N*-dimethylformamide (144). In the latter case it was noted that substitution with deuterium on the methyl group of the formamides lowered the GC retention time, but that its presence in the formal position increased retention time. GC isotopic fractionation of deuterated analogues has also been published for such ethers as tetrahydrofuran (145), where a cobalt (II) complex was employed, and di-2-butylether (146). The GC separations of several deuterated TMS carbohydrate derivatives (147-150) along with deuterated glucose and mannose (151) from unlabeled compounds have also been studied.

Other diverse deuterated compounds useful to life science investigators have manifested isotopic fractionation on GC including several examples of deuterated acids, amino acids or their TMS derivatives (152-156). It was found that deuterated TMS nucleoside analogues exhibited GC separation from their unlabeled counterparts (157). The deuterated analogues of uridine and cytidine were earlier

eluting but it was concluded that the degree of separation for each had more to do with structural considerations than label content. Other compounds labeled with deuterium such as TMS quinoxalins (158), caffeine and its metabolites (159, 160), iproniazid (161), aminopyrine (162), isopropylantipyrine (163), verapamil (164), desipramine (165, 166) and fentanyl (167) have all displayed some degree of GC isotopic fractionation.

Deuterated lipids and leukotrienes have also been the subject of GC isotopic fractionation studies. Deuterated fatty acid esters (168, 169) and metabolites of deuterated linoleic and linolenic acids (170) and deuterium labeled acetanilides of 6,9-octadecadiene (171) all displayed isotopic fractionation. Also, [$^2\text{H}_6$] valproic acid (172) and [$^2\text{H}_6$] 4-ketovalproic acid (173) separated on GC from the corresponding unlabeled compounds while a slight GC separation was noted between [$^2\text{H}_6$] LTB₄ and LTB₄ (174). Larger deuterated compounds like steroids have displayed GC isotopic fractionation from unlabeled counterparts too. [$^2\text{H}_6$] Testosterone (175) and [$^2\text{H}_6$] cholesterol (176) are such examples.

Although deuterated compounds have dominated the published instances of isotopic fractionation by GC, compounds labeled with tritium have also provided examples. By means of recycle GC, tritiated cyclobutane was separated as an earlier eluting peak from cyclobutane (73). Using a glass capillary column at low temperature the separation of CH_4 , CH_3^3H , CH_2^3H_2 , CH^3H_3 and C^3H_4 (increasing retention time) was reported (88). Curiously, the elution order was reversed using a charcoal column at low temperature (177). Other reports on the separation of tritiated methane isotopomers have appeared (178, 179) including one (180) which described the preparation and GC purification of C^3H_4 on a multi Curie scale. Other workers succeeded in the GC separation of several tritiated propane and butane isotopomers (181) and small reductions in the retention time of several compounds labeled with tritium including cyclohexane, cyclohexene, heptane and benzene compared to unlabeled compounds were noted (182). As with deuterated olefins, silver nitrate-ethylene glycol GC columns have promoted the separation of several tritiated olefins (183). A degree of GC isotopic fractionation has also been reported for larger tritiated molecules. Several tritiated lipid methyl esters have displayed some separation from their cold counterparts by GC (184, 185). Also,

monitoring the $^{14}\text{C}/^3\text{H}$ effluent ratio on the GC of certain tritiated steroids indicated that they were somewhat separated from their carbon-14 analogues (186).

Besides hydrogen isotopes, carbon isotopes have also demonstrated fractionation on GC. A small separation was noted for fatty acids labeled with carbon-14 (165). Also, a measure of GC separation has been observed for $^{13}\text{CO}/^{12}\text{CO}$ (187-189) and $^{12}\text{CO}_2/^{13}\text{CO}_2$ (190, 191), $^{12}\text{CH}_4/^{13}\text{CH}_4$ (192, 193) and $^{12}\text{CF}_4/^{13}\text{CF}_4$ (194). The investigation of isotopic fractionation for $^{12}\text{CH}_4/^{13}\text{CH}_4$ in ref. 193 is intriguing because it was prompted by the disparate ratios of these isotopomers in samples taken at various locations in a southern Italian gas field. The authors used Bentonite as a GC solid support to mimic what they propose was geological isotopic fractionation. Isotopic fractionation by GC for fatty acid methyl esters and other compounds labeled with carbon-13 has also been observed (195, 196). The GC isotopic fractionation of $^3\text{HCH}_4$ from methane facilitated the improvement of its specific activity (197, 198), and a degree of GC isotopic fractionation was also reported for some nitrogen-15 labeled compounds (199).

VIII. High Pressure Liquid Chromatography

The most recent chromatographic technique to provide examples of isotopic fractionation is high pressure liquid chromatography (HPLC). In this area, reports of the phenomenon emerged almost simultaneously for both tritium and deuterium labeled compounds. With tritium, among the earliest examples reported were the reverse phase HPLC isotopic fractionation of the polycyclic aromatics [^3H] 7,12-dimethylbenz[a]anthracene, [^3H] benzo[a]pyrene and analogues (200-202). In these instances the tritiated material often eluted earlier than the cold standard. The HPLC of arachidonic acid metabolites on silver ion loaded columns also exhibited isotopic fractionation, with the separation of the earlier eluting unlabeled deuterated or carbon-14 compounds from the later eluting tritiated analogues (203-205). The authors proposed a unique and compelling explanation for the observation (see Section IX). Further reports concerning the HPLC isotopic fractionation of [^3H] arachidonic acid and other eicosanoids labeled with tritium followed (206-210), with several of the authors reflecting on the implications of the

phenomenon for biological assays. In the last reference Do and coworkers summarized over a decade of observations made in their laboratory on such separations for both normal and reverse phase HPLC with a variety of immobile phases. On reverse phase HPLC several tritiated steroids (55, 211) and on both normal and reverse phase HPLC a number of tritiated Vitamin D analogues displayed isotopic fractionation (212-216). Several of the authors noted that the degree of separation was influenced by tritium location. Worth (216) also speculated that the pronounced isotopic fractionation could be exploited to elevate the specific activity of tritiated Vitamin D metabolites.

Tritiated nucleosides and related compounds have also been studied. [^3H] Thymine (217) and [^3H] thymidine (218) analogues as well as [^3H] 2'-deoxyguanosine (219) were reported to separate on HPLC from unlabeled standards. The Kudelin group in St. Petersburg has employed isotopic fractionation on preparative HPLC to enhance the specific activity of tritiated nucleosides (220). In this account, specific activities were significantly increased with selective fraction collection of earlier eluting labeled compounds. [^3H] Dopamine (221) has also exhibited isotopic fractionation on reverse phase HPLC. This thorough study explored the influence of tritium location on separation and would appear to be one of the earliest accounts of the phenomenon for catecholamines. The drug substances [^3H] bepridil (222), [^3H] imipramine, [^3H] desipramine (223) and [^3H] N-0437 (224), and the macrocycle [^3H] tetrahydroechinocandin B (225) have also displayed HPLC peak fractionation. In the first two examples the authors noted a marked effect on peak separation in conjunction with the proximity of tritium to nitrogen. In contrast, the last example, initially disclosed at an October 1990 Merck hosted International Isotope Society meeting, is remarkable for the degree of separation provided by tritium in an extended alkyl chain location of the macrocycle remote from any heteroatom.

Several [N-methyl- ^3H] radioligands have also afforded interesting cases of HPLC isotopic fractionation. On normal phase HPLC eluted with dichloromethane:methanol (98:2), we found that the elution order of (+-) mianserin analogues were unlabeled (+-) mianserin, (+-)-[N-methyl- ^3H] mianserin and finally (+-)-[N-methyl- ^3H] mianserin (226). The simultaneous use of both UV detection and liquid scintillation flow monitoring facilitated our measurement of isotopic

fractionation in this study. On reverse phase HPLC both [N-methyl- ^3H] chlorpromazine (227) and [N-methyl- ^3H] SKF (R) 83566 (228) demonstrated analogous HPLC separation. Interestingly, the retention time of the former radioligand was longer than the unlabeled standard while that of the latter was shorter than unlabeled standard on reverse phase HPLC. Also in the earlier study, no isotopic fractionation was reported for [benzene ring- ^3H] chlorpromazine and the degree of isotopic fractionation for [N-methyl- ^3H] chlorpromazine was significantly dependent upon pH.

For deuterated compounds the first example of HPLC isotopic fractionation recorded would seem to be the separation of long chain perdeutero carboxylic acids (earlier eluting) from unlabeled standards on reverse phase by Thornton and Tanaka (229, 230). Baseline peak separation was noted for palmitic acid and perdeuteropalmitic acid prompting the authors to suggest the significance of their findings for possible preparative scale utility. Motivation for this study of the isotope effect during "hydrophobic binding" was its possible role as a model for similar interactions in biomembranes. [^3H] Methyl palmitate was separated from unlabeled standard employing a recycle technique on silver nitrate impregnated silica gel HPLC (231). This and similar methodology was later applied to other deuterated fatty acids (232, 233).

HPLC isotopic fractionation of monodeuterobenzene (234) as well as perdeuterobenzene (235-242), perdeuterotoluene (235, 238, 242, 243) and ethyl benzene (244) have been described. In most cases the deuterated compound eluted earlier than the unlabeled one. In one of these reports (239) it was concluded that deuterated water was superior to water for the HPLC separation of deuterated aromatics from unlabeled compounds, enhancing the separation by as much as 30%. Other deuterated aromatic compounds also have been investigated including [^3H] benzoic acid (245, 246). In the first study it was apparent that the position of deuterium labeling had a significant effect on the degree of fractionation observed, with ortho substitution being far less influential for separation than meta or para substitution. The author was inclined to propose a steric rather than electronic explanation for the observation. In the case of several aromatic aldehydes labeled

with deuterium on the aldehyde carbonyl, Yu and coworkers have described their HPLC separation from unlabeled compounds (247-249).

Other deuterated aromatic compounds reported to exhibit isotopic fractionation include [^2H] naphthalene 2-sulfonic acid (250), several deuterated polycyclic aromatics (251), [^2H] dopamine (252), [^2H] epinephrine and [^2H] norepinephrine (253) and [^2H] indole-3-acetic acid (254, 255). Several deuterated steroids (208, 256) and eicosanoids (204, 205, 257) have shown a degree of HPLC isotopic fractionation. Also the vitamin A metabolic precursor B-carotene, when deuterated, was found to separate with baseline resolution from unlabeled compound on reverse phase HPLC (258, 259), and in both reports the labeled compound eluted earlier. In the second study the authors showcased the results as an opportunity for other investigators without access to a mass spectrometer to study the dynamics of absorption and metabolism of [^2H] B-carotene in humans.

Deuterated drug type compounds have provided further examples of HPLC isotopic fractionation. These include [^2H] N-0437 glucuronide (224) several deuterated caffeine (260), [^2H] methadone (261), and some deuterated benzodiazepines and related compounds (236, 262-264). The effect of pH was noted as influential in some of these separations (262, 263). Also investigated were the tricyclic [N-methyl- ^2H] imipramine (265) and the tetracyclic [^2H] mianserin (266, 267). In this latter example it was clear that only deuterium substitution on the piperazine ring of mianserin would promote the observed separation. The Organon group also investigated the related compound [^2H] Org GC-94 (268) which on normal phase eluted later than the unlabeled compound. In this case the more acidic the eluent, the better was the observed peak separation. Other examples of related HPLC isotopic fractionation include [^2H] carbamazepine (269), [^2H] CCNU analogues (270) and [^2H] roxatidine acetate metabolites (271) and [^2H] bepridil (222).

Various other deuterated compounds have also been reported to display isotopic fractionation including [^2H] tetrahydroechinocandin B (225) and several [^2H] gibberellins (272). In this latter case the labeled gibberellins eluted slightly ahead of the endogenous substances on reverse phase HPLC. Even the pigment chlorophyll (one of the earliest substances to be studied chromatographically by

Tswett) when deuterated, has demonstrated some striking reverse phase HPLC isotopic fractionation (273-275). Using the mobile phase water:methanol:acetonitrile:tetrahydrofuran (5:28:38:23) with a flow rate of 1 mL/min, Baweja reported that [^2H] chlorophyll *a* eluted two minutes ahead of the unlabeled compound (273). Reverse phase HPLC also accomplished the separation of [N-methyl- ^2H] FTC-methylamine (276) as well as some perdeuterated diglucosyldiacylglycerols (277) from their unlabeled counterparts.

Other isotopes besides hydrogen have provided examples of HPLC fractionation. Both [^{14}C] trioleoylglycerol (278) and [^{14}C] leucine (279) appeared to separate from unlabeled standards. Further examples are [^{13}C] theophylline metabolites (280), [^{13}C] leucine (281), the antiviral compound [^{13}C] LY-217,896 (282), [^{13}C] decanal (283), some organic acids labeled with carbon-13 (284) and [^{13}C] methyl palmitate (285). Tanaka and coworkers have elegantly explored the isotopic fractionation of both nitrogen-15 and oxygen-18 labeled compounds. Although not completely resolved, significant HPLC separations of [^{15}N] aniline (286, 287), and [^{15}N] N-methylaniline and [^{15}N] N,N-dimethylaniline (287, 288). Others have reported similar HPLC isotopic fractionation of [^{15}N] chlorophyll (289). Tanaka has also reported the HPLC isotopic fractionation of the several isotopomers of [^{18}O] benzoic acid (290-292), [^{18}O] 4-chlorobenzoic acid (292) and [^{18}O] 4-nitrophenol (287, 292).

Perhaps the most intriguing aspect of isotopic fractionation for HPLC or any other chromatographic method has been very recently reported; namely, chromatographic separation based on the chirality conferred by isotopic content as initially reported by the Tanaka group (293-295). Indeed, in his first paper (293) Tanaka cited the fact that prior claims of diastereomeric separation based on isotopic influence have been challenged (296). In this demonstration of chiral isotopic fractionation, diastereomers of [phenyl- ^2H] methyl 3-diphenylglycidate were separated on reverse phase HPLC as three peaks with the perdeuterated species eluting first. The center peak containing the two diastereomeric pairs created by single phenyl ring deuteration was separately caught and injected onto a chiral HPLC column whereby enantiomer separation was observed. Another equally compelling example of this phenomenon was reported recently by Pirkle (297).

disclosing that deuterated enantiomers of a pivalamide were separated in a chiral supercritical fluid HPLC experiment.

IX. Causes of Isotopic Fractionation

Although a great deal of effort has been expended in documenting various instances of isotopic fractionation, less time has been spent in explaining its mechanism. Indeed, after considering all the published work on the subject, it appears that a number of factors, varying in importance and each additive or subtractive in contributing to peak separation, may be operative. However, when considered collectively, these factors should adequately explain the elution order of substances differing only in isotopic content.

Mass:

In most cases the mass difference between isotopically labeled and unlabeled compounds alone has been dismissed as playing any significant role in isotopic fractionation. Isotopic substitution in many of the compounds reviewed here alter their molecular weight by only a few percent at best. However, the GC elution order of $^{12}\text{CH}_4$, $^{13}\text{CH}_4$, and $^{14}\text{CH}_4$ was consistent with their increasing mass differences (88).

Steric Considerations:

One would think that steric effects produced by the isotope itself would rarely be invoked as a cause of isotopic fractionation. However, a persuasive explanation advanced for the isotopic fractionation of some deuterated and tritiated compounds is a steric one; namely, the lowered zero point vibrational frequency and resulting decrease in the Van-der-Waals radius of the series H , ^2H , ^3H (298), and the increasingly shorter carbon-hydrogen isotope bond length in the series C-H , $\text{C-}^2\text{H}$ and $\text{C-}^3\text{H}$. For instance: 1) On a silver nitrate-ethylene glycol GC column, the deuterated isotopomers of ethylene (101, 104) and propylene (101) can be separated. 2) On a silver nitrate-silica gel column, [9, 10, 12, 13- ^3H] methyl linoleate migrated more slowly than the unlabeled standard (23). 3) On a silver nitrate impregnated normal HPLC column, [1- ^{14}C] PGE₂ eluted faster than [5, 6, 8, 11, 12, 14, 15- ^3H] PGE₂ (203). An explanation for all three of the foregoing separations is that the

decreasing C-H, C-³H and C-²H bond lengths allowed increasing interaction between the complexing silver ions of the solid support and the olefins of the isotopomers in question. It has been observed that the stability of silver ion-olefin complexes increased when the hydrogen atoms were replaced by deuterium (299). In this same study it was also noted that such silver ion-olefin complexes were more stable when deuterium was actually attached to the olefin bond rather than merely adjacent to it. Therefore, it can be argued that the progressive substitution of deuterium or tritium for hydrogen would retard to a greater degree the migration of an olefin on a silver ion loaded column. A similar explanation may be operative for the inclusion mechanism based separation of deuterated compounds in ref. 26 and the HPLC separation of deuterated benzoic acid isotopomers (245).

Vapor Pressure:

The vapor pressure of a labeled and unlabeled compound can differ (300-303). For instance, the vapor pressure of a deuterated compound is generally higher than that of the corresponding unlabeled compound (304). Certainly, this circumstance could be a factor influencing isotopic fractionation by GC.

Polarity:

The alteration of an atom's polarity by an adjacent isotope has been cited as the cause of some of the most intriguing instances of isotopic fractionation. From the work of Robertson (305, 306), it would seem that the substitution of deuterium or tritium on a carbon atom bearing a nitrogen would cause the nitrogen to be more basic than its unlabeled counterpart. During silica gel chromatography, the amine would more strongly deprotonate the weakly acidic Si-OH groups and thus retard the elution of the labeled compound relative to the unlabeled one. Obviously, this effect would be more pronounced in neutral or basic eluents, but in systems acidic enough to protonate all amines, such isotopic fractionation would normally be minimal. Polarity has also been suggested for the observed HPLC isotopic fractionation of aldehydes substituted at their carbonyl with deuterium, potentially altering their hydrophobic interaction with the reverse phase chromatographic system (247-249).

X. Implications

Having reviewed the many examples and probable causes of isotopic fractionation during the past several decades it is appropriate to briefly consider its implications. Clearly isotopic fractionation when considered over the entire experience of labeled compound chromatography is still a rare but certainly precedented observation and should only be invoked cautiously. If it is operative and not taken into account then significant errors can corrupt the measurements made with labeled compounds such as specific activity (33), various assays (209, 211) and mass spectrometry techniques (307). Awareness of it can prompt the use of an alternate label that does not display the phenomenon. Furthermore, isotopic fractionation has been exploited to facilitate various measurements including physical adsorption (91, 92), the dynamics of complexation (110), GC-MS analysis (154) and partition coefficient determination (241). It has also been used to substitute for more costly analyses like GC-MS (259) and provide models for such systems as biomembranes (229, 230).

Curve Fitting for Restoration of Accuracy for Overlapping Peaks in Gas Chromatography/Combustion Isotope Ratio Mass Spectrometry

Keith J. Goodman and J. Thomas Brenna*

Division of Nutritional Sciences, Cornell University, Ithaca, New York 14853

The effect of graded degrees of overlap on high-precision and -accuracy carbon isotope ratios determined by gas chromatography/combustion isotope ratio mass spectrometry (GCC/IRMS) is reported. Overlapping peaks of closely matched isotope ratio (difference $\delta^{13}\text{C}_{\text{PDB}} < 1\%$) were analyzed by the conventional vertical drop summation algorithm and by curve fitting using the Levenberg-Marquardt algorithm. The conventional algorithm resulted in systematic bias related to degree of overlap even though precision was not noticeably affected. The exponentially modified Gaussian (EMG) and Haarhoff-VanderLinde (HVL) functions were found to model GCC/IRMS peaks satisfactorily. Useful models over a wide range of overlap were obtained by applying consecutive HVL/HVL or HVL/EMG functions to overlapping peaks. Accuracy was improved in most cases and was never degraded. This study demonstrates the presence of subtle bias in isotope ratio determinations of overlapping peaks and the ability of automated curve fitting to compensate for these biases.

High-precision compound-specific isotope analysis (CSIA) is rapidly becoming an important tool in a variety of fields as diverse as organic geochemistry and biomedicine. Gas chromatography/combustion isotope ratio mass spectrometry (GCC/IRMS) and the recent introduction of liquid-based CSIA¹ facilitate online separation, combustion, and analysis of carbon isotopes in organic molecules. CSIA has been used primarily to investigate small changes in carbon isotope ratios that occur due to natural processes,^{2,3} although recently the technique has been used for enriched species as well.^{4,5}

In GCC/IRMS, CO_2 generated by combustion of GC effluent is analyzed by a multicollector mass spectrometer. CO_2 is continuously monitored at masses 44 ($^{12}\text{C}^{16}\text{O}_2$), 45 ($^{13}\text{C}^{16}\text{O}_2 + ^{12}\text{C}^{17}\text{O}^{16}\text{O}$), and 46 ($^{12}\text{C}^{18}\text{O}^{16}\text{O}$). A peak in each detector trace appears for each eluting compound, and thus each trace resembles the output of a flame ionization detector (FID). At the conclusion of the run, software must identify peak start/stop, subtract background levels, calculate peak areas, and calculate area ratios according to theoretical considerations.⁶ Highly precise and accurate isotope ratio determinations depend on consistent peak and background definitions for each of the three detection channels. Total

error (precision and accuracy) for isotope ratios determined in this way is routinely less than 0.05% relative standard deviation (RSD) for well-resolved peaks.

Analysis of complex mixtures often results in overlapping chromatographic peaks. Specific requirements for auxiliary preparation devices (e.g., furnaces, dryers) for GCC/IRMS results in a large number of connectors between the chromatography column and the detector, which influence peak shape and generally reduce chromatographic efficiency.^{7,8} Resolution is also limited by the restriction of He as carrier gas, compared with H_2 . As a result, mixtures that are fully resolved by conventional GC-FID are not resolved by GCC/IRMS. For these reasons, chromatography in GCC/IRMS tends to be more subject to overlaps than conventional GC.

Mathematical curve fitting for quantitative analysis of overlapping peaks has been reported extensively in the chromatography literature. Curve fitting for well-resolved peaks is thought to offer several advantages over summation methods, including straightforward definition of peak limits and less susceptibility to noisy baselines.⁹⁻¹¹ Previous studies focused on single detector systems and have the explicit purpose of providing improved quantitative results compared with nonfitting techniques. To date, no systematic studies of the effect of overlap on high-precision isotope determinations by GCC/IRMS have appeared.

Traditional chromatograms may be thought of as a collection of well-resolved singlets with a few doublets of varying degrees of overlap. The recovery of information from doublets is the subject of this work. It is assumed that triplets and higher multiplets, although rare according to theoretical considerations,¹² will be resolved chromatographically.

Several characteristics of a curve-fitting algorithm are desirable. (1) The algorithm should be "rugged". That is, it should yield acceptable results over a wide range of operating conditions, preferably in an automated system. (2) It must run rapidly with reasonable hardware requirements. (3) It should be useful over a wide range of overlap encountered for real samples. (4) Finally, it should improve analytical figures of merit for most peaks; those that it does not improve it

should not degrade. We report here an experimental study of the effects of overlapping peaks on accuracy and precision of GCC/IRMS-determined isotope ratios and a curve-fitting strategy applicable to recovery of isotope information from overlapping peaks.

EXPERIMENTAL SECTION

Instrumentation. A Finnigan MAT 252 high-precision GIRMS instrument interfaced to a Varian 3400 GC via a ceramic combustion furnace was used for the analysis. A detailed description of this instrumentation can be found elsewhere.⁴ Briefly, the effluent from the capillary GC column enters a furnace and is combusted quantitatively to CO₂. After drying, analyte-derived CO₂ is admitted into the electron impact ion source of the high-precision GIRMS system. The mass spectrometer is operated at its full accelerating potential of 10 kV and a source chamber pressure of 4×10^{-6} Torr. Faraday cup detectors with dedicated amplifiers and counters continuously monitor each of the three major ion beams. For this work, the integration time was 0.25 s, as is routine in our laboratory. The GC was operated with the injector ($T = 250$ °C) in split mode with a split ratio of 20:1 and He carrier flow of 45 cm/s through the column. A J&W DB-WAX 30 m \times 0.32 mm \times 0.5 μ m fused silica capillary column was used. The oven temperature program was isothermal.

Test Chromatograms. Methyl tridecanoate (Me13:0) and butylated hydroxytoluene (BHT; Sigma Chemical Co, St. Louis, MO) were used as test compounds. Stock solutions of each pure component were prepared in bulk and used throughout the experiment to ensure the isotopic integrity of the samples. Mixtures were prepared from the stock solutions in the mass ratios 1:1, 10:1, and 1:10. These ratios were chosen as representative of the extremes of mass ratios to which this work applies. Also, for integration routines that employ both perpendicular drop and tangent-skim algorithms, an absolute abundance ratio of 10 commonly represents the decision threshold between the two methods.¹³ Concentrations were adjusted to 5 μ g/ μ L for each component of the 1:1 mixture and the more abundant components of the unequal mixtures (1:10 and 10:1). The concentrations of the less abundant components of the unequal mixtures were adjusted to 0.5 μ g/ μ L. An injection volume of 1 μ L yielded a peak signal of 3.5 V in the mass 44 channel for the 1:1 components and the major components of the unequal mixtures.

Graded degrees of overlap may be produced by double injection or by manipulation of chromatographic parameters. The chief advantage of double injection, used primarily for liquid chromatography (LC), is optimal preservation of peak shape.¹⁴ This approach is not practical for GC since peaks are sharp and maintaining reproducibility of overlap is difficult. For this reason, graded overlap was produced by increasing the column temperature from 220 to 250 °C for isothermal runs. This method generated highly reproducible overlap for the eluting compounds by degrading resolution. Peak shapes were not noticeably different for individual compounds run at each temperature, although least-squares fits did show some small distortion, as reflected by r^2 . This distortion was well within that observed for injection of widely differing quantities

under identical conditions. The degree of overlap is expressed as "%valley", calculated as $100(\text{valley height})/(\text{peak height})$.¹⁴ Conditions were established to produce 10, 40, and 70% valley for the 1:1 mixture. A 70% valley is observed in dense chromatograms of complex mixtures and should be particularly useful for GCC/IRMS applications to enriched tracer molecules requiring lower precision. The 10:1 and 1:10 mixtures were analyzed under each set of conditions used for the 1:1 case, and in subsequent discussion are designated 10, 40, or 70% valley with respect to the 1:1 case. Pure compounds were run separately under conditions used for 10% valley and plotted as "0% valley". Me13:0 eluted first under these conditions.

Data Analysis: Conventional Method. Data was analyzed by the conventional method using vendor-provided software (Finnigan ISODAT). The peak detect algorithm processes only one data channel for the detection and definition of peak start and stop. Peaks are detected by calculating the slope of a rolling regression line drawn through five consecutive data points and comparing the result to a user-defined threshold slope ("slope sensitivity"). Peak stops are set when the slope falls below threshold, after a peak start has been detected. The slope sensitivity was set to a single intermediate value that produces satisfactory results in our hands for well-resolved peaks at signal-to-noise ratios above ~ 50 . Backgrounds are determined as the average of four adjacent points beginning five points before the start of the peak. Once the peak start and stop have been defined for a single channel, the values are extrapolated to the other two channels. Peak maxima are determined for all channels and a time shift is used to correct for chromatographic separation of isotopes.^{3,15} Peak areas are calculated by summing the difference between baseline and signal for the region defined by the peak start and stop. Ratios and associated calculations are made using areas produced for each peak.¹⁶ For overlapping peaks, the valley minimum is assigned as the leading peak stop and the trailing peak start. When applied to overlapping peaks, the routine resembles the "perpendicular drop" method.^{11,13} Summing of consecutive readings between peak limits after subtraction of baseline is referred to as the "summation" method.¹⁷

The ratios of areas corresponding to individual components are taken for each trace (44, 45, and 46) to produce R45 (area 45/area 44) and R46 (area 46/area 45). R45 and R46 are both required for calculating $\delta^{13}\text{C}$, as R46 is used for an ^{17}O correction that subtracts the contribution of [$^{12}\text{C}^{17}\text{O}^{16}\text{O}$] to the m/z 45 signal.⁶ For compounds of low oxygen content, such as those considered here, most of the O of CO₂ is derived from the combustion furnace and is therefore invariant. The small contribution from the test compounds, Me13:0 and BHT, is also of identical isotopic composition within experimental error. Calculations show that relatively large changes in the mass 46 channel do not appreciably alter the $\delta^{13}\text{C}$ calculations. For these reasons, and to simplify the calculations for the curve fitting, traces of mass 44 and 45 only were fitted and the data will be presented without correction for ^{17}O .

The standard notation for expression of high-precision gas isotope ratio mass spectrometry results is the $\delta^{13}\text{C}$ notation,

(17) Anderson, D. J.; Walters, R. R. *J. Chromatogr. Sci.* 1984, 22, 353-359.

which requires the ^{17}O correction. In this work, we use $\delta 45$ defined as

$$\delta 45 = \left(\frac{R_{\text{SPL}} - R_{\text{PDB}}}{R_{\text{PDB}}} \right) \times 1000 \quad (1)$$

where R_{SPL} and R_{PDB} are the m/z 44 and 45 signal ratios corresponding to the sample and standard, Pee Dee Belemnite, respectively, with $R_{\text{PDB}} = 0.011\,237\,2 \pm 0.000\,009\,0$.¹⁸

Data Analysis: Curve Fitting. Raw data files were converted to ASCII files, containing four columns of data corresponding to time, and counts (arbitrary units) for each of three detectors m/z 44, 45, and 46. A BASIC program was then used to split the data files into three separate files, each containing time and one of the signals. Data fitting was performed using a Compaq 386/20e desktop computer equipped with a math coprocessor, 4 Mbytes of RAM, and a 210-Mbyte hard drive. The DOS computer program Peakfit 3.0 (Jandel Scientific), an implementation of the Levenberg-Marquardt algorithm, was used for all curve fitting.¹⁹ Given a set of initial values, this algorithm systematically searches parameter space to find parameters yielding the minimum error sum of squares. A single chromatogram was fitted manually using each of several test chromatographic functions to establish initial parameter values. These values were then used as initial values for all subsequent fits. Chromatograms for each detection channel were fitted in a batch-processing mode using several functions. The batch mode permits a user-selectable prefit routine that fits every other point as a rapid "coarse" fit, followed by fine adjustments using all the data. This procedure results in more rapid fitting than use of all the data from the outset. Each function is expressed using peak area as an independent, adjustable parameter. Isotope ratios were calculated from the best-fit peak area parameter.

A variety of functions have been proposed for modeling of chromatographic peaks; therefore it was necessary to determine which functions most satisfactorily modeled GCC/IRMS data. Functions were evaluated based on the fit parameters r^2 and mean square ratio (F statistic), and comparing the calculated mass and area ratios to the known ratios of the mixtures. Time for fitting was also taken into account.

Chromatographic elution profiles previously have been modeled as a Gaussian distribution. Under real chromatographic conditions, peaks are often skewed and not modeled well by symmetric functions such as a Gaussian.²⁰⁻²⁴ Peak models that take asymmetry into account improve accuracy and precision relative to symmetric models.²⁵⁻³² The exponentially modified Gaussian (EMG) function, a mathematical convolution of a Gaussian with an exponential decay, has

proven to be an acceptable model for real (asymmetric) chromatographic peaks, especially when extra column effects are present.^{10,33} The form of this function is

EMG

$$f(x) = \frac{a_0}{2a_3} \exp \left[\frac{a_2^2}{2a_3^2} + \frac{a_1 - x}{a_3} \right] \left[\operatorname{erf} \left(\frac{x - a_1}{2^{1/2}a_2} - \frac{a_2}{2^{1/2}a_3} \right) + 1 \right] \quad (2)$$

where a_0 is area, a_1 is elution time, a is width of the Gaussian, a_3 is the exponential constant which determines distortion in this model, and erf is the error function. Estimates of peak area, chromatographic efficiency, and maximum attainable efficiency, can be obtained from these function parameters.^{28,29,31} The EMG model, one of the most commonly employed chromatographic functions for modeling GC peaks, has also been successfully applied to situations where baseline resolution has not been achieved.³³⁻³⁵

Other functions considered here are the (a) Haarhoff-VanderLinde (HVL), which was developed for nonideal gas chromatography and is capable of modeling peaks that exhibit "fronting" or tailing,²⁵ (b) Giddings (GID), a function designed for conditions in which diffusion and extracolumn effects are absent and different kinetic rates of adsorption and desorption are the primary sources of band broadening,³⁶ and (c) nonlinear chromatographic (NLC), which was recently considered for modeling ideal δ function analyte loading.³⁷ The forms of these equations are as follows:

HVL

$$f(x) = \frac{a_0 a_2}{a_1 a_3 (2\pi)^{1/2}} \frac{\exp \left(-\frac{1}{2} \left(\frac{x - a_1}{a_2} \right)^2 \right)}{\left[\exp \left(\frac{a_1 a_3}{a_2^2} \right) - 1 \right] + \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{(x - a_1)/a_2}{2^{1/2}} \right) \right]} \quad (3)$$

GID

$$f(x) = \frac{a_0}{a_2} \frac{a_1^{1/2}}{x} I_1 \left(\frac{2(a_1 x)^{1/2}}{a_2} \right) \exp \left(\frac{-x - a_1}{a_2} \right) \quad (4)$$

NLC

$$f(x) = \frac{a_0}{a_2 a_3} \left[1 - \exp \left(-\frac{a_3}{a_2} \right) \right] \left[\frac{\frac{a_1^{1/2}}{x} I_1 \left(\frac{2(a_1 x)^{1/2}}{a_2} \right) \exp \left(\frac{-x - a_1}{a_2} \right)}{1 - \exp \left(-\frac{a_3}{a_2} \right)} \right] \quad (5a)$$

Figure 1. Signal from mass 44 channel illustrating signal decay of GC peak and CO₂ standard after closing of a valve. The GC signal decays ~3-fold slower than that resulting from the valve closing.

$$T(u, v) = e^{-u} \int_0^v e^{-t} I_0((2vt)^{1/2}) dt \quad (5b)$$

where a_0 is peak area, a_1 is elution time, a_2 is peak width, a_3 is distortion (for HVL and NLC), and I_n are modified Bessel functions of the first kind.

Peak Shapes. The degradation of chromatographic efficiency by dead volumes has been considered previously.^{7,8} Most chromatographic detectors are placed at the exit of the chromatography column to minimize dead volumes and unnecessary broadening due to diffusion after the separation. In GCC/IRMS instrumentation, additional connections are required to interface the capillary column with the mass spectrometer. In the present instrument, this corresponds to eight connections between the GC column and the mass spectrometer and includes two changes in tubing diameter to accommodate a furnace and water trap. An open split, a device used to moderate pressure, is placed in-line prior to the mass spectrometer and peak shape is sensitive to the flow at this split. Finally, the tight ion source of GIRMS instruments is designed to maximize residence time, in order to maximize sensitivity.

The net effect of this hardware is to distort peak shapes appreciably from that emerging from the GC column. The trailing section of a sharp, fast-eluting, well-behaved GC peak is plotted in Figure 1, along with the falloff in signal from closing of the valve that admits calibrated CO₂ directly to the ion source. The half-life for the calibrated CO₂ signal is $t_{1/2} = 170$ ms compared with $t_{1/2} = 530$ ms for the peak and demonstrates that the ion source responds more rapidly to changes in signal than required for most capillary GC peaks. The source of peak broadening resides in the chromatographic separation and interface, rather than the mass spectrometer ion source.

RESULTS AND DISCUSSION

The chromatograms for the various test mixtures and degrees of overlap are presented in Figure 2. The absolute retention times from chromatogram to chromatogram have been adjusted for comparison purposes but the peak shapes and widths with respect to time are unaltered.

Single Peaks. The four separate functions, EMG, GID, HVL, and NLC were screened for goodness of fit and fitting time. Both the r^2 and F statistics are commonly employed to evaluate goodness of fit. R^2 alone is not sufficient to define the quality of fit, as it is an index of noise as well as degrees of freedom in the model relative to the number of data

Figure 2. Chromatograms for the three mixtures and three overlap conditions investigated in this work. Me13:0 elutes prior to BHT in these chromatograms.

Table 1

| | r^2 | F |
|-----|---------------------|---------------|
| EMG | 0.999 48 ± 0.000 26 | 41864 ± 14615 |
| HVL | 0.997 85 ± 0.000 77 | 9627 ± 2779 |
| NLC | 0.997 86 ± 0.000 76 | 9762 ± 2837 |
| GID | 0.991 20 ± 0.003 74 | 4167 ± 3820 |

* Mean ± SD ($n = 6$).

points.^{38,39} The F statistic, however, is adversely affected by irrelevant degrees of freedom in the model.³⁸ Therefore, both the r^2 and F statistics were calculated to evaluate goodness of fit, and residuals were plotted for inspection.

Six typical chromatograms were fitted with each function to evaluate the appropriate function to model GCC/IRMS peaks. No less than 40 data points were used for each fit. The data are presented in Table 1 as means and standard deviations. The EMG fits resulted in significantly greater mean r^2 and F statistics (pairwise t , 95% confidence). The residual plots for the EMG fits were random. The HVL and NLC resulted in comparable fits, which were poorer than the EMG. Inspection of the residuals indicated that the peak tail was not modeled well for either the HVL or NLC. In addition, the NLC function required 66 s per mass channel compared with 25 s for the H function, a substantial 2.6-fold difference. The GID function gave the poorest fit based on both r^2 and F , as might have been anticipated based on the assumptions of that model and the present application. The isotope ratios calculated from fits with each function did not reveal any clear trend in absolute value or precision. Based on these results, the GID and NLC functions were eliminated from further consideration and the EMG and HVL functions were applied to unresolved peaks. For convenience, we refer to these functions by their first letters in the following.

Fitting Characteristics of Overlapping Peaks. The E and H functions were screened for goodness of fit for overlapping peaks. In addition to r^2 and F , the accuracy of the peak area ratios was used as an index of goodness of fit. At higher degrees of overlap the EE combination broke down. (XY refers to the application of function X to the first eluting peak

Figure 3. Best fit for the application of the EMG/EMG function combination to a 1:1, 70% valley chromatogram. The tail of the leading EMG function extends into the second peak, leading to erroneous abundance and isotope ratios.

Figure 4. (a, top) Best fit for the HVL/HVL combination to a 10:1, 70% valley chromatogram. The leading edge of the trailing HVL function extends into the first peak. (b, bottom) Best fit for the HVL/EMG combination to the same data.

of a doublet, with Y applied to the trailing peak.) The EE fit of the 1:1 70% valley is presented in Figure 3. This fit resulted in a superior r^2 and F statistic compared with the HH combination. The first E function, however, distorts and tails excessively into the second peak, resulting in inaccurate peak areas. In contrast, the HH combination yielded a poorer r^2 but better estimates for the peak areas. Application of the HH combination to the other overlap chromatograms revealed that the HH combination did not provide accurate estimates for the 10:1 70% valley, shown in Figure 4a. The area for the second H peak area was overestimated because it fronted into the first peak to compensate for inability of the H function to model the tail of the first peak. Since the E was susceptible to errors due to excessive tailing and the H due to fronting, the HE combination was tested. A plot of the HE combination model for a 10:1 70% valley is presented in Figure 4b. In this plot, all experimental points are coincident with those of the model. This combination did not show any obvious fronting or tailing distortions for any of the conditions and, therefore, was used along with HH and EE for fitting all overlaps. The fourth and remaining combination of EH was evaluated for completeness.

The nine overlap conditions of Figure 2 were fitted by use of each of these four combinations of functions. Three or four replicate chromatograms were obtained and fitted for

Figure 5. Isotope ratios obtained by summation and fitting for equal abundance mixtures. Open symbols refer to summation data and are repeated in all cells for comparison. Closed symbols refer to fitted data. Circles refer to Me13:0, which elutes earlier than BHT, represented by squares. Error bars are 95% confidence limits (using t statistic).

each overlap condition. Fits were evaluated for quality of (a) isotope ratios and (b) single-channel (m/z 44) area ratios, for quantitative analysis. To evaluate accuracy, results were compared to those obtained by summation and offline combustion. All differences in means were tested for significance by use of the pairwise t test at a 95% confidence level.⁴⁰

Isotope Ratios: Equal Abundance. Figure 5 presents R_{45} and corresponding δ_{45} obtained by summation and fitting for the four combinations of functions. Each data point represents a mean of at least three replicates fitted independently. The summation data are repeated in each cell for convenient comparison. Error bars represent 95% confidence limits, and when absent, they are contained within the symbol. The δ_{45} s and standard deviations for these data are presented in Table 2.

Isotope ratios for all degrees of overlap are significantly different when determined by summation than for 0% valley and appear to be systematically related to degree of overlap. At 70% valley, the apparent isotope ratio of the leading peak (Me13:0) is depleted by about $\delta_{45} = \sim 10\%$, while the isotope ratio of the trailing peak (BHT) is enriched by a corresponding level. This unexpected result is observed even though the difference in carbon isotope ratio between these compounds is only $\delta_{45} = -0.30$. It is significant to note that the precision for most of these highly inaccurate ratios is not seriously degraded, suggesting that precision is not a good indicator for accuracy for the summation method.

Fitted and summation data for the leading peak at 0% valley are not significantly different for any of the functions. Significant differences were detected for 0% valley trailing peak using the EE and EH fits ($\delta_{45} = -26.67 \pm 0.189$) compared with summation data ($\delta_{45} = -27.51 \pm 0.097$).

For all function combinations, the fitted ratios are of significantly improved accuracy relative to the summation ratios for 10 and 40% valley. All functions except the EE combination resulted in improved accuracy at the 70% level.

^a $\delta 45 \pm$ SD.

The EE combination gives very poor precision at 70% valley. The E function is known to break down at high degrees of overlap (>45% valley), and so this result is consistent with previous reports. This appears to be due to the tendency of this function to tail excessively from the leading peak into the trailing peak. The EH combination is consistent with this interpretation as it results in the poorest precision and accuracy at the 40% valley. Isotope ratios determined using the EE and EH functions cross over between 10 and 40% valley. In contrast, the HE and HH functions recover isotope ratios similarly to one another and more accurately than the other combinations. The isotope ratios for the HE and HH cross over between 40 and 70% valley. For this data set these functions appear to provide superior recovery of isotope ratios.

We have previously considered the accuracy of GCC/IRMS carbon isotope determinations referenced to conventional combustion and dual-inlet GIRMS analysis.⁴ An offset of up to $\delta^{13}\text{C} = 1\%$ is observed for GCC/IRMS analyses referenced to calibrated CO_2 . For this reason, the use of isotopically calibrated standards within the chromatography mixture has been suggested.⁴ In any case, the offset observed for fitted data up to 40% valley is small and within this accuracy limit.

Isotope Ratios: Unequal Abundance. Fit and summation results for the 10:1 mixture is shown in Figure 6a. The scaling is identical to that used in Figure 5 for comparison, and again the summation results are plotted for all fitting combinations. The summation peak detection algorithm detected two peaks for the 40% valley in only a single case and failed to detect two peaks for any of the 70% valley replicates. However, the presence of the smaller peak significantly lowered the calculated isotope ratio for the large peak in the 10% case. In the single 40% valley case the presence of the smaller peak altered the major peak by $\delta 45 = \sim 2\%$. The summation results for the smaller peak result in substantially greater degradation of both precision and accuracy than for the larger peak.

Figure 6. Isotope ratios obtained by summation and fitting for the (a, top) 10:1 and (b, bottom) 1:10 abundance mixture. The symbol key is given in the legend to Figure 5.

No significant differences are detected between fitted and summation ratios for either 0 or 10% valley for the leading peak, while the EE and EH combinations provide similar ratios, which significantly improve the accuracy of the smaller trailing peak. The HE and HH combinations give similar results for which isotope ratios are reversed relative to the other combinations. Not for any fitted case is the accuracy degraded relative to summation.

Data for the 1:10 mixture is presented in Figure 6b. In this case, the summation peak detect algorithm successfully identified all peaks. Summation and fitted ratios for the larger trailing peak are significantly different at the 0% valley only. In contrast to the 10:1 case, the precision and accuracy of the isotope ratio of the larger peak is affected by less than 1% for all degrees of overlap using the summation method.

For the smaller leading peak, summation ratios for all degrees of overlap are significantly different from the 0% valley, and the trend toward lower isotope ratios is significant, though smaller than the trend of the smaller peak in the 10:1 data. At the 10 and 40% valleys, the improvement in ratio for the fitted data is statistically significant.

Quantitative Analysis. Ratios of fitted peak areas for the mass 44 channel were constructed to evaluate the preservation of quantitative information. Area ratios were constructed for summation and fitted data using the leading peak in the numerator and are presented graphically in Figure 7 for the equal abundance data (1:1). The summation ratios show a

Figure 7. Area ratios for the equal abundance data calculated using the mass 44 signal: Me13:0/BHT, 1:1. Error bars are 95% confidence limits. Closed symbols refer to fitted results: EE (triangle), HE (circle), HH (square), and EH (diamond); open squares refer to summation results.

few percent bias (low) relative to the fully resolved case. The four fitted combinations result in a systematic trend for which the 10% valley ratios are slightly underestimated, with overestimation for the higher degrees of overlap. The order of overestimation is $EH > EE > HH > HE$, and the best accuracy is obtained with the HE combination. Precision degrades with increasing overlap in all cases.

The confidence limits plotted in Figure 7 are constructed from the standard deviations of the pooled replicates for each fit and, when calculated in this way, are not significantly different from the 0% valley. However, close inspection of the data reveals that most of the variability could be attributed to random variation from run to run, which could not be attributed to variation in signal or injection volume. Therefore, each of six differences in means among the four combinations was calculated for each replicate, and the resulting *mean differences* were tested as significantly different from zero. In every case, except one with particularly high variability, differences were found to be significant between combinations (95% confidence limits). This indicates that quantitative analysis using curve fitting is sensitive to choice of function. The four differences were calculated between the summation results and each function. Differences for all combinations except HE were statistically significant. The HE combination data at the 10 and 70% valleys were not statistically different from the summation results and were marginally significant ($P < 0.03$) at the 40% valley. These results indicate that quantitative information is best preserved by the HE combination under these conditions.

Mass 44 area ratios for fitting of the unequal abundances are presented in Figure 8. Figure 8a shows the area ratios resulting from 10:1 data set. As expected, the precision is substantially poorer than in the 1:1 case. However, mean differences in area ratio are more dramatic than in the 1:1 case, as many of the mean ratios are statistically different. As expected, most area differences (14 of 18) were statistically significant. The summation ratio is severely underestimated for both degrees of overlap for which there are data (10 and 40%). The 10% valley is the only overlap in which there are replicate summation data, and they are not statistically different from any of the fits.

Figure 8b presents the 1:10 data. Here all ratios are systematically shifted to lower values as a function of overlap and there is much better agreement among fits and summation. None of the areas resulting from these fits are significantly

Figure 8. Area ratios for unequal abundance data calculated using the mass 44 signal: Me13:0/BHT of (a, top) 10:1 and (b, bottom) 1:10. The symbol key is given in the legend to figure 7.

different from the summation data. However, all but one fit is statistically different from one another at 10% valley. At the higher degrees of overlap only 1 of 12 comparisons was statistically significant.

These results indicate that choice of functions is important for trailing smaller peaks at all degrees of overlap; for leading small peaks the choice of functions is important only for low degrees of overlap. This difference in behavior in both isotope ratio and abundance calculations for the unequal abundance mixtures probably arises because of the asymmetric shape of the GCC/IRMS peaks considered here. In nearly all regards, the 1:10 mixture is better behaved than the 10:1 mixture, suggesting that the large tail in the latter case is not optimally modeled by these functions. Functions show a tendency to compensate for deficiencies in the modeling of the remaining peak. This was shown dramatically earlier and probably operates here on a subtle level. The overall greater effectiveness of the HE combination over the wide range of overlaps and abundance ratios may be due to the resistance of the H function to tail and the E function to front. The HH combination was also highly effective but was less effective than HE in some cases.

CONCLUSIONS

Overlapping peaks detected by conventional algorithms are systematically distorted in isotope ratio even for closely matched compounds, though high precision is maintained. Further, small trailing peaks can significantly affect the apparent isotope ratio of the major peak. Curve fitting is effective in restoring isotope ratios for overlap as high as 70% valley, and its effectiveness depends on the relative abundances and elution order as overall peak areas become more unequal. In none of the cases investigated did the fitted data result in poorer accuracy than the conventional summation method; the fitted data were either improved or not degraded. Our data indicate that the HVL/EMG or HVL/HVL combina-

tions provide the best fits of the functions considered in detail and are most robust and rapid for automated fitting of GCC/IRMS chromatograms. Small trailing peaks are the most difficult to model, apparently because they are obscured by the tail of the preceding peak. Small leading peaks are more easily modeled, and their minor effects on the major trailing peak can be effectively removed within the experimental error of these measurements. Finally, chromatographic peak shapes depend on specific chromatographic configuration and conditions, for which other functions may yield improved performance.

Summary

An isotope ratio mass spectrometer and an ion trap mass spectrometer have been coupled in parallel to one gas chromatograph. Using this arrangement both the $^{13}\text{C}/^{12}\text{C}$ ratio and the mass spectrum of a given compound can be measured simultaneously under identical gas chromatographic conditions. Although column connection fittings are employed to split the capillary eluate, chromatographic performance was barely impaired. Development of the system has been monitored by recording $\delta^{13}\text{C}$ values of the constituents of Grob test mixture no. 2. The accuracy and reliability of system performance has also been tested.

1 Introduction

Since the introduction of isotope ratio mass spectrometers (IRMS) coupled on-line to a gas chromatograph (GC) via a combustion interface (C), there has been an increasing interest in their analytical applications [1–5]. The merits of such systems are, however, somewhat limited because any statement about the isotopic composition of a given compound is exclusively based upon its gas chromatographic identification. When analyzing complex mixtures, such as plant extracts or physiological fluids, containing components present in an extremely wide range of concentrations, reliable measurement of isotopic composition is, furthermore, severely hampered by loss of column performance resulting in bad peak shape and insufficient separation. One solution to this problem is multidimensional GC-IRMS [6]. Another approach is to use thick-film capillary columns, which combine high resolution with good capacity [7].

All disciplines of analytical chemistry usually deal with mixtures of at least partly unknown composition. Not only unknown compounds of potential diagnostic value but also actually known compounds should and must be unambiguously identified. However accurate, the GC-C-IRMS technique only provides information on isotopic composition of a given compound. Identification of compounds relies solely upon retention indices. For unambiguous identification, repetition on another conventional GC-MS system is necessary, yet this solution is tainted with some uncertainty.

The logical step was to develop a system providing the means to obtain both mass spectrometric information and information about isotopic composition under identical gas chromatographic conditions, as described previously [8]. Maintaining the high

resolution achieved is absolutely essential for obtaining reliable measurements of isotopic enrichment. Owing to the unique design of the GC-C-IRMS, splitting of the GC eluate proved to be the most critical step. Difficulties encountered here most recently, prompted some modification in this respect.

2 Experimental

2.1 Instrumentation

The major components of the new system are a Varian model 3400 GC, a Delta S isotope ratio mass spectrometer (IRMS), a combustion interface, and a Magnum ion trap mass spectrometer (ITD); all, except for the GC, were designed and manufactured by Finnigan MAT. The ITD was chosen because its unique properties in respect of its vacuum and sample size requirements made it the most suitable candidate. The IRMS equipment, namely an oxidation oven and a reduction oven in the combustion interface, together with 2×3 Faraday cups for recording masses 44, 45, 46, and 28, 29, 30, respectively, enables the measurement of either ^{13}C or ^{15}N enrichment.

Uncoated deactivated fused silica capillaries of various length and internal diameter were chosen as connecting components in a way that in direct mode, i.e. with both back-flush valves closed, the split ratio was 20:1 between the combustion interface and ion trap outlet, respectively. This split ratio best meets the different needs of the two mass spectrometers. About 95 % of the GC eluate enters the combustion interface because the IRMS needs ca 1 nmol carbon in its ion source to ensure reliable results. About 5 % of the GC eluate enters the ITD because even in full scan mode sample amounts of 1 to 100 pmol are sufficient for this system.

To prevent solvent peaks entering the combustion oven, Matthews and Hayes [9] used a single solvent bypass valve linked to a vacuum pump. The state of the art Finnigan GC-C-IRMS system comes with a back-flush device which basically consists of two valves switchable in parallel. When open, in a direction opposite to that of normal carrier gas flow, helium is directed into the combustion furnace at about 2 ml/min. Part of this device is a Valco T-piece placed between column and combustion oven. One of the outlets is connected to one of the two back-flush valves which is open in back-flush mode; the other outlets are connected to the end of the capillary column and a fused silica capillary leading into the combustion oven, respectively.

¹ Present address: University of Dundee, Department of Anatomy and Physiology, Dundee DD1 4HN, UK.

To split the GC eluate, first a Valco cross-piece (Valco Instruments Europe, Schenkon, Switzerland) and later cross pieces manufactured by Gerstel (Gerstel GmbH, Mülheim, Germany) were employed. All the cross pieces have virtually no dead-volume but exhibit different properties in respect of leak tightness and thermal mass.

The connectors used for the coupling to the ITD are manufactured by Scientific Glass Engineering (SGE GmbH, Weiterstadt, Germany). The capillary coming from the cross piece, an additional helium make up capillary, and the capillary leading to the transfer line of the ITD were mounted in the connectors to form an open-split interface as previously described in detail [8]. The additional helium make-up is necessary because, in contrast to magnetic sector and conventional quadrupole MS which operate under high vacuum conditions, e.g. 10^{-6} mbar, an ITD requires a critical helium pressure, ca 10^{-2} mbar, in the ion trap for reliable operation.

2.2 Testing Conditions

All tests were performed under standardized conditions. Helium was used as carrier gas and its linear velocity was set to 28.6 cm/s. A 40 m \times 0.32 mm glass capillary column coated with a 0.32 μm film of OV-1701-OH and a 30 m \times 0.25 mm fused silica capillary column coated with a 1 μm film of DB-5 (J&W) were used. Sample volumes were 1.2 and 2.1 μl for the OV-1701 column and DB-5 columns, respectively. The split ratio was set to 1:20. The oven temperature was held at 40 $^{\circ}\text{C}$ for 5 min and then programmed to 280 $^{\circ}\text{C}$ at 4 $^{\circ}\text{C}/\text{min}$. Column test mixture 2 according to Grob (Fluka, Neu-Ulm, Germany) was used throughout all experiments.

A dichloromethane solution (3 nmol/ml) of a mixture of authentic methyl esters of organic acids (*RS*)-methyl lactate, methyl (*R*)-3-hydroxybutyrate, dimethyl glutarate, methyl phenylacetate, and methyl laurate (Fluka) was analyzed to check the system for potential influence of GC eluate splitting on measurement of isotopic composition compared with direct mode operation using a T-piece.

The oxidation and reduction ovens of the combustion interface of the IRMS were operated at 940 and 600 $^{\circ}\text{C}$, respectively. In back-flush mode, helium was directed into the combustion furnace at 2 ml/min to prevent, e.g., solvent peaks entering the combustion oven and thereby prematurely exhausting its oxidation capacity.

3 Results and Discussion

3.1 Valco Cross-Piece

In first attempts to couple an ITD in parallel to an IRMS a Valco cross-piece was substituted for the Valco T-piece [8]. Initial Grob tests performed using temperature gradients of 1 $^{\circ}\text{C}/\text{min}$ and less [10] looked rather promising. With temperature gradients of 2 $^{\circ}\text{C}/\text{min}$ and more, however, considerable loss of chromatographic performance was observed (Figure 1). Owing to drastic peak broadening none of the polar compounds in the test mixture could be detected by the IRMS. Having passed the combustion furnace their corresponding carbon dioxide peaks disappeared in the m/z 44 baseline.

Figure 1. GC analysis of the test mixture on OV-1701-OH, using a Valco cross-piece as capillary eluate splitter. (A) Reconstructed ion chromatogram (RIC) obtained on the ITD; (B) ion current of m/z 44 (carbon dioxide) simultaneously recorded on the IRMS with calculated 45/44 ratio-trace; D, 2,3-butanediol; C10, *n*-decane; C12, *n*-dodecane; P, 2,6-dimethylphenol; S, 2-ethylhexanoic acid; A, 2,6-dimethylaniline; Am, diethylohexylamine; E0-E12, methyl esters of decanoic, undecanoic, and dodecanoic acids.

Furthermore, in contrast with the claimed leak tightness up to temperatures of 300 $^{\circ}\text{C}$, the Valco cross-piece started to leak even after one run ending at e.g. 280 $^{\circ}\text{C}$. More precisely, it was leak tight up to 280 $^{\circ}\text{C}$ but after cooling to 40 $^{\circ}\text{C}$ leaks were detected at all four connecting screws. The formerly tightened screws had worked themselves loose, possibly as a result of thermal expansion of the solid metal body of the cross-piece.

This behavior substantiated the idea that the high mass (15 g) of this cross-piece was also the reason for its observed influence on chromatographic performance. Owing to the extreme peak broadening of the polar constituents of the test mixture and the peak tailing of the fatty acid methyl esters, it was believed that the Valco cross-piece acted as cold spot.

When extreme peak broadening and peak tailing were first observed all obvious sources had been checked. Capillary columns were double-checked for chromatographic performance on a GC (HRGC 5300 Mega Series, Carlo Erba) and a GC-MS (Varian GC 3400-TSQ 70, Finnigan). Injector inserts and all connectors were deactivated prior to use by treatment with 1 ml of a 1:1 (v/v) mixture of dimethylchlorosilane and hexamethyldisilazane in *n*-heptane (50 ml). In the meantime fused silica connecting cap-

Figure 2. GC analysis of the test mixture on OV-1701-OH, using a standard Gerstel cross-piece as capillary eluate splitter. (A) RIC of the ITD. (B) ion chromatogram of the IRMS. Asterisks indicate reference gas peaks. Peak identification as for Figure 1.

illaries deactivated with a 1 nm coating of OV-1701-OH were used [11].

3.2 Standard Gerstel Cross-Piece

Prompted by the aforementioned observations an alternative to the Valco cross-piece had to be found. As a result of good experience with Gerstel 3D capillary column connectors in respect of leak tightness, low dead volume, and influence on chromatographic performance a Gerstel 3D cross-piece seemed suitable.

The standard Gerstel cross-piece weighs 5 g. Figure 2 shows a GC chromatogram of the test mixture obtained after substitution of the Gerstel cross-piece for the Valco cross-piece. Although the test chromatogram now showed all the polar compounds, there was still room for improvement. S and Am were, for instance, still relatively small and broad and could not, therefore, be detected with the IRMS.

In contrast to the Valco cross-piece, the Gerstel cross-piece stayed leak tight even after repeated analyses ending at 300 °C. No difference in nitrogen, argon, and water levels between separate analyses could be detected on either mass spectrometer.

3.3 Custom-Made Gerstel Cross-Piece

The next logical step was to design a light-weight cross-piece by literally cutting down on material without losing stability. To meet this requirement, Gerstel produced a custom-made cross-piece weighing 3.18 g only.

Figure 3A shows that the resulting test chromatogram bears virtually no difference from a test chromatogram obtained when the capillary column was installed directly into the transfer line of the ITD (Figure 3B). When these two reconstructed ion chromatograms (RIC) are compared more closely, slight peak tailing can be observed in Figure 3A. This is certainly caused to a certain extent by the cross-piece. Most of this effect is, however, a consequence of the manner in which the chromatograms are depicted, i.e. by proportional amplification of ubiquitous peak tailing as both RICs are normalized to the most intense peak. In Figure 3B the ion current of the baseline is ca 8700 whereas in Figure 3A it is ca 1200. So, in Figure 3B the ubiquitous peak tailing is pushed into the base line. When the peak tail ion currents were compared relative to the corresponding baseline ion currents it was found that peak tailing in Figure 3A was only 30 % greater than the ubiquitous peak tailing.

Figure 3. GC analysis (RIC) of the test mixtures on DB-5, using (A) the light-weight Gerstel cross-piece as capillary eluate splitter and (B) when the column end was installed directly into the ITD transfer line. Peak identification as for Figure 1.

When leak tightness was checked, the customized cross-piece showed the same properties as the standard cross-piece. This cross-piece has since been used for more than 200 analyses ending at 300 °C without the need for retightening or changing of a seal.

3.4 System Performance and Reliability

Obviously, reliable GC-C-IRMS requires good GC performance because both precision and accuracy of IRMS measurements are limited by chromatographic resolution. Table 1 lists $\delta^{13}\text{C}$ values of the constituents of Grob test mixture 2; these clearly demonstrate the influence of this on accuracy. Differences in peak shape and, hence, in peak integral width from one analysis to another, yield $\delta^{13}\text{C}$ values showing standard deviations of nearly 0.1 %. Although accuracy and precision improve with as the influence of the cross-pieces on GC performance is reduced, no significant shift in $\delta^{13}\text{C}$ values can be observed.

To check the system for reliability, i.e. for potential isotopic fractionation as a result of GC eluate splitting, a mixture of methyl esters of five organic acids was analyzed on the original GC-C-IRMS (direct coupling *via* T-piece) and on the hybrid system with GC eluate splitting *via* the light-weight cross-piece. This mixture was chosen because comparable chromatographic behavior on both systems could be expected for all compounds except for the two hydroxy acids which showed extreme peak broadening on the original GC-C-IRMS system. Comparison of $\delta^{13}\text{C}$ values obtained on the original and hybrid systems (Table 2) revealed no evidence of isotopic fractionation.

4 Conclusion

Coupling an IRMS and an ITD in parallel to one GC by means of a light-weight cross-piece and a home-made open-split connector resulted in a hybrid GC-MS system which makes it possible both to determine isotopic composition and to obtain structural information by recording mass spectra of any given compound simultaneously in one GC analysis with virtually no loss of chromatographic performance. Peak tailing in addition to ubiquitous peak tailing amounts to approximately 30 % at the most. Shifting of $\delta^{13}\text{C}$ values as a result of isotopic fractionation was never observed.

This hybrid system combines the sensitivity of an IRMS for isotopic enrichment and the trace sensitivity of an ITD in one system, opens a new line of applications for isotope ratio mass spectrometry, and improves the conclusiveness of existing applications. All areas of research and applied analytical chemistry, e.g. food quality control, nutritional sciences, environmental monitoring, toxicology, and biomedicine will profit from the potential of this system.

SHORT COMMUNICATION

Bridging the Information Gap Between Isotope Ratio Mass Spectrometry and Conventional Mass Spectrometry

An isotope ratio mass spectrometer and an ion trap mass spectrometer were coupled in parallel to one gas chromatograph. This system provides the means to obtain information about both chemical nature and isotopic composition of a given compound under identical gas chromatographic conditions.

INTRODUCTION

Since the introduction of isotope ratio mass spectrometers (IRMS), on-line coupled to a gas chromatograph (GC) via a combustion interface (C), there has been increasing interest in its various analytical applications.¹⁻⁵ The merits of this system, however, are somewhat limited because the statement about the isotopic composition of a given compound is exclusively based upon its unambiguous gas chromatographic identification.

This demand can only be met in cases of injection of either single compounds or not too complex mixtures. Otherwise, the identification of single peaks becomes biased, as it relies solely on comparison of retention indices as well as the assumption that each peak is caused by one compound only.

In all disciplines of analytical chemistry one usually deals with mixtures of at least partly unknown composition. Not only unknown compounds of potential diagnostic value but also actually known compounds should and must be unambiguously identified. Additionally, sometimes only a very limited amount of material to be investigated is available. The GC/C/IRMS technique requires at least 1 nmol carbon in the ion source. Therefore, repetition of the analysis on another conventional GC/MS system may not be possible. Furthermore, this is not an acceptable solution of the problem. Slight changes in carrier gas flow, non-identical GC oven conditions, replacement of columns and variation in the concentration range of the sample, to name but a few, are typical sources of error that strongly influence GC performance and hence hamper reproducibility and reliability of an analysis.

† Author to whom correspondence should be addressed.

The logical step is to devise a system providing the possibility of obtaining both mass spectrometric information and knowledge about isotopic composition under identical gas chromatographic conditions. Here, we wish to present such a system where an IRMS and an ion trap mass spectrometer are coupled in parallel to one GC.

MATERIALS

The major components that comprise the new system are a Varian GC, model 3400, a Delta S isotope ratio mass spectrometer, a combustion interface and a Magnum ion trap mass spectrometer, all manufactured and designed by Finnigan MAT except for the GC. The ion trap mass spectrometer was chosen because its unique properties with respect to its vacuum and sample size requirements made it the most suitable candidate.

For connecting those components, uncoated deactivated fused-silica capillaries of various internal diameters were used. The cross-piece that splits the effluent coming from the GC column is made by Valco Instruments Co. Inc. This cross-piece has virtually no dead volume and its fittings are leaktight. The connectors used for the coupling to the ion trap mass spectrometer are made by Scientific Glass Engineering Pty Ltd (S.G.E.).

RESULTS AND DISCUSSION

In order to prevent solvent peaks entering the combustion oven, and thereby prematurely exhausting the oxidation catalyst, Matthews and Hayes⁶ used one solvent bypass valve that was linked to a vacuum

pump. The state-of-the-art Finnigan GC/C/IRMS system comes with a backflush device that basically consists of two valves switchable in parallel. When open, in the opposite direction towards the carrier gas flow, helium is directed into the combustion furnace at about 2 ml min^{-1} (Fig. 1). Part of this device is a Valco cross-piece placed between column and combustion oven (Fig. 2). One of the two remaining outlets is con-

nected to one of the two backflush valves that is open in backflush mode; the other outlet, connected to a fused-silica capillary, is permanently open. To this outlet the ion trap mass spectrometer was linked.

The internal diameters of the capillaries involved are chosen in such a way that in straight mode, i.e. both backflush valves closed, the split ratio combustion interface to ion trap outlet is 9:1, as this split ratio meets

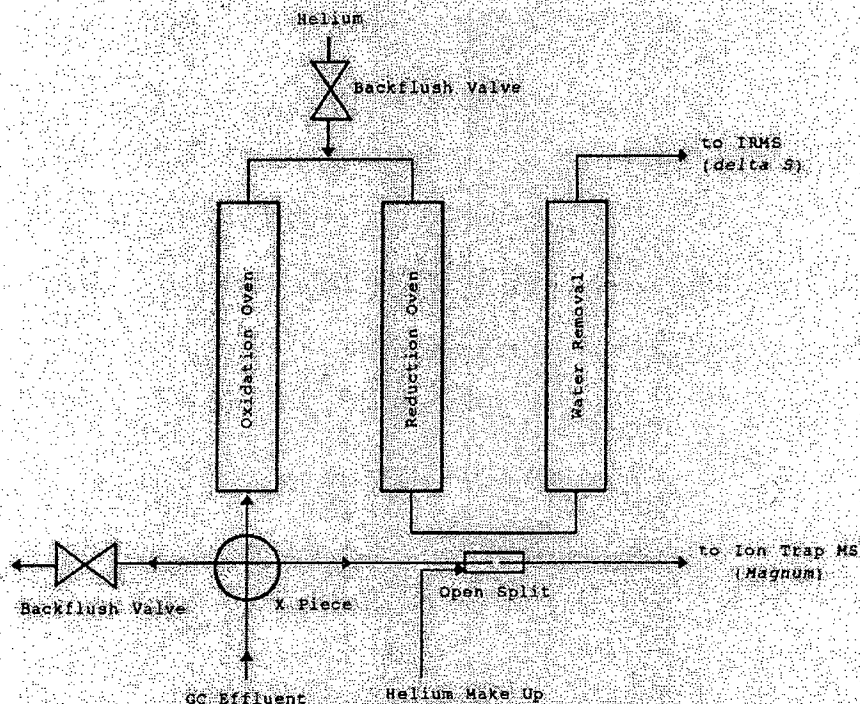

Figure 1. Schematic layout of the combustion interface with backflush device and coupling to the isotope ratio mass spectrometer and the ion trap mass spectrometer.

Figure 2. Cross-section through the Valco cross-piece that serves as split. Note that internal diameters of capillaries are not identical.

Figure 3. Sketch of the open split connector to the ion trap mass spectrometer.

best the different needs of the two mass spectrometers. About 90% of the GC effluent enters the combustion interface because the IRMS needs an amount of about 1 nmol carbon in its ion source to ensure reliable results. About 10% of the GC effluent enters the ion trap mass spectrometry, because for this system sample amounts of 1–100 pmol are sufficient.

Whereas the outlet leading to the combustion interface is directly connected to the combustion furnace, the capillary leading to the ion trap mass spectrometer is integrated into an open split⁷ that basically consists of two SGE linear connectors (Fig. 3). In contrast to magnetic sector and conventional quadrupole mass spectrometers which operate under high vacuum conditions, an ion trap mass spectrometer requires a certain helium pressure, i.e. 10^{-3} mbar, in the ion trap to operate reliably. For that, an additional helium make-up is led to one of the aforementioned connectors by a second capillary. Both capillaries are mounted into the left side of the first connector by a two-hole ferrule. The carrier gas capillary is completely led through this connector and finally ends in a fused-silica capillary that is mounted into the right side of the connector. The make-up capillary, however, is only introduced halfway into the connector, thus forming a constant helium cushion around the carrier gas capillary and inside the surrounding capillary. From its open end, the mass spectrometer interface capillary, mounted straight through a second SGE linear connector, is introduced to meet the carrier gas capillary in the middle of the surrounding capillary, leaving a gap of less than 1 mm between them.

In backflush mode the amount of sample material entering the ion trap mass spectrometer is considerably smaller, however. As the backflush is generally used to cut out solvent peaks, this loss of information can be

tolerated. Usually, acquisition of mass spectroscopic data is started after elution of the solvent peak anyway.

None of the aforementioned connecting parts, i.e. cross-piece and SGE connectors, causes detectable loss in chromatographic performance due to cold spots. The system has been tested using Grob-test mixture no. 2 on three capillary columns coated with stationary phases of different polarity and different film thickness, e.g. 0.17 μ m HP Ultra 1, 1.0 μ m J & W DB-5, 0.3 μ m OV 1701-OH. In straight mode, reconstructed ion currents for constituents of 1.5 μ l Grob-test mixture No. 2, injected in split mode 1 to 10, are in the range of 30 000–260 000.

CONCLUSION

We think the system will open a new line of applications for isotope ratio mass spectrometry and will improve the conclusiveness of existing applications. Sample preparation up to now involving several steps, each bearing the risk of isotopic fractionation,⁸ can be simplified. Peaks, unexpectedly showing isotopic enrichment, e.g. in tracer studies of biochemical pathways, can be identified by on-line recording their mass spectra.

In short, all the areas of research and applied analytical chemistry, where stable isotope labelled compounds or detection of small changes in isotopic composition are involved, will profit from the potential of such a system.

High-precision gas chromatography–combustion isotope ratio mass spectrometry at low signal levels

Keith J. Goodman, J. Thomas Brenna*

Division of Nutritional Sciences, Cornell University, Ithaca, NY 14853, USA

First received 30 August 1994; revised manuscript received 7 October 1994

Abstract

Precision and accuracy of gas chromatography–combustion isotope ratio mass spectrometry are investigated for sample levels down to about 5 pmol C in fatty acid methyl ester mixtures spanning 1000-fold in concentration. Precision and accuracy of isotope ratios diverge rapidly for conventional summation methods, and become unusable below 30 pmol material on column. At lower levels, mean isotope ratios were statistically different from reference values indicating bias as well as poor precision. In contrast, curve fitting, using the exponentially modified Gaussian line shape, gives improved precision for most peaks and useful results down to 3 pmol. The curve-fitting algorithm was also less sensitive to signal integration time than the summation method. These data indicate that curve fitting may be the method of choice for integration of noisy data when high-precision isotope ratios are desired.

1. Introduction

High-precision gas [1,2] (or liquid [3,4]) chromatography–combustion isotope ratio mass spectrometry (x-C–C-IR-MS) for analysis of C or N isotopes [5,6] is gaining importance across many areas of natural science [7]. These techniques facilitate the analysis of individual compounds at very small sample sizes, with precision levels approaching that of conventional dual inlet [8]. Most applications take advantage of these improved parameters, as well as the capability to rapidly obtain high-precision compound-specific results without cumbersome chemical separation prior to analysis (e.g. Refs. [9–11]). However, a wide variety of applications require the analysis of complex mixtures, inevitably involving over-

lapping peaks. We previously reported that the conventional summation integration algorithm produces systematic bias at degrees of overlap as low as 10% valley, even for compounds of well matched isotope ratio (e.g. $\Delta\delta^{13}\text{C} < 0.5$) [12]. Most notably, this bias is observed while high precision is maintained. Further, isotope ratios for minor components (<10 ng) are seldom calculated because of overlaps and the well known difficulties in defining peak start/stop in low signal-to-noise ratio (S/N) cases. This is true even though high-precision results ($\delta^{13}\text{C} < 0.5$) can be achieved for sub-ng sample sizes under ideal circumstances [8].

We have recently shown that curve fitting can be effective in recovering accurate isotope ratios from severely overlapping peaks while preserving high precision [12]. Curve-fitting methods are known to be more resilient to low S/N than

* Corresponding author.

summation algorithms, where peak definition is most difficult [13–15]. Analysis of low levels by GC–C-IR-MS is of particular interest for tracer studies where precision as poor as $\delta^{13}\text{C} < 100$ is useful for detecting enriched metabolites [2]. We report here a systematic study comparing curve fitting to conventional summation for well-resolved small sample injections over four orders of magnitude in single GC–C-IR-MS chromatograms.

2. Experimental

2.1. Instrumentation

A Varian 3400 GC system interfaced to a Finnigan MAT 252 high-sensitivity gas isotope ratio mass spectrometer via a combustion interface was used for this study. The instrument was operated at an accelerating potential of 8 kV and a source pressure of $2 \cdot 10^{-6}$ Torr (1 Torr = 133.322 Pa). Briefly, the effluent of the capillary column is directed to a combustion furnace held at 850°C and loaded with CuO as a source of O_2 . Combustion products are dried and pass through an open split prior to entrance to the IR-MS ion source. CO_2 is monitored continuously at m/z 44, 45 and 46 with three dedicated faraday cups and associated electronics. Asymmetric peak shapes are commonly observed because of the numerous connections and changes in capillary diameter between the GC column and the mass spectrometer. Details of the system can be found elsewhere [2].

A fatty acid methyl ester (FAME) standard mixture was separated on a J & W (Folsom, CA, USA) DB-23 capillary column, (30 m \times 0.32 mm I.D., 0.25 μm film). Carrier flow through the GC column was 45 cm/s He (99.999 + %), with inline O_2 and H_2O traps. Fatty acid standards were obtained from Sigma (St. Louis, MO, USA) and were 99 + % pure by GC analysis. Hexane (Fisher Optima grade) was used whenever solvent was necessary, and samples were stored in glass vials with Teflon-lined caps. The test mixture was composed of methyl pentadecanoate (Me15:0), methyl heptadecanoate

(Me17:0), methyl octadecanoate (Me18:0) and methyl heneicosanoate (Me21:0) at concentrations of about 0.16, 1.6, 16 and 160 ng/ μl , respectively. Injections of 0.5 μl of this mixture were made in splitless injection mode. A second, equimolar mixture of these compounds (0.2 $\mu\text{g}/\mu\text{l}$ each) was prepared and analyzed separately to establish reference isotope values for each compound.

The vendor-supplied data acquisition system collects a signal from each mass channel simultaneously for adjustable integration times. At the conclusion of an integration period, a counter is queried, zeroed, and restarted, giving a >99% duty cycle. Any particular integration time is a tradeoff between noise per data point and faithful reproduction of lineshape. Longer integration times improve S/N for each data point, but distort lineshape. This distortion can be important for accurate curve fits, as well as for precise definition of peak start/stop for summation. The test mixture was analyzed using integration times of 0.25, 0.125 or 0.0625 s to investigate the effect of this parameter on summation and on curve-fitting peak integration approaches. Four or five replicates were made at each integration time.

2.2. Data processing

The vendor-provided software "ISODAT" (Finnigan MAT, Bremen, Germany) was used to process the data by the summation method. A review of this software has been published recently [16]. Slope sensitivity (SS) for peak start/stop definition is set by the user. A rolling five-point linear least squares fit is applied to the chromatogram, with peak start defined when the slope exceeds the SS; stops are defined as the point beyond the peak where the slope falls below the absolute value of the SS. SS settings chosen to detect strong peaks and reject spurious noise-related peaks do not satisfactorily detect very small peaks, while settings used to detect small peaks are overly sensitive to noise. Therefore, two separate settings for slope sensitivity were compared, SS = 0.8 mV/s for higher level detection which has performed satisfactorily in

routine applications in our laboratory over the last three years, and $SS=0.1$ mV/s for low detection. Other workers report $SS=1$ mV/s as satisfactory for routine analyses [8].

The commercial program Peakfit (Jandel Scientific) was used for all curve fitting. Previously, we evaluated several functions for use with GC-C-IR-MS peaks [12]. The well-known exponentially modified Gaussian (EMG) function, constructed as the mathematical convolution of the Gaussian and exponential functions [15], accurately reproduces the line shapes as long as the column is not overloaded and appears to work particularly well for low signal levels. It was used exclusively in this work. Each set of four or five chromatograms for each integration time were processed with the $SS=0.8$, $SS=0.1$, and curve-fit methods.

As in previous work, we calculate high-precision isotope ratios according to the following:

$$\delta 45 = \left(\frac{R_{SPL} - R_{PDB}}{R_{PDB}} \right) \times 1000 \quad (1)$$

where R_x is the ratio of integrated areas for the m/z 45 to 44 channels, SPL and PDB refer to the sample and the international standard Pee Dee Belemnite, respectively, international standard with $R_{PDB} = 0.0112372$. This expression does not take into account the contribution of $^{12}C^{16}O^{17}O$ to the m/z 45 signal, which is small and in the case of GC-C-IR-MS is nearly constant. Areas are obtained by either fitting the m/z 44 and 45 channels or using the summation methods. No outliers were excluded from this data set.

Tests of statistical differences of means were performed using the t -distribution at the 95% confidence level [17].

3. Results and discussion

A representative chromatogram is presented in Fig. 1, and plotted in semilog format so that the four orders of magnitude peak intensities and background noise levels are discernable. Peak intensities above baseline range from about 2 mV for the smallest, earliest eluting peak to a high of

Fig. 1. GC-C-IR-MS chromatogram of the FAME test mixture plotted in semilog format.

500 mV for the most abundant but broader, latest eluting peak. There is a significant amount of chemical noise near the intensity of the smallest peak, which corresponds to 0.1% of the largest peak, Me21:0. As all FAMES in the mixture are 99+ % pure, contaminants at this level entering the test mixture with Me21:0 are expected. Signal outputted in volts by the data system was converted to current, and peak area in nA s was calculated and used for comparison.

Deviations from reference values in $\delta 45$ units (%) are presented in Figs. 2–4 for the individual determinations of FAMES at the three integration times investigated. The abscissa represents signal area and is approximately logarithmic, although points have been offset horizontally for illustrative purposes. Both summation methods diverge more rapidly than the fitted data as sample size decreases for all integration times. Performance of the summation methods degrades significantly at 63 ms integration time compared with the 125 and 250 ms case. In contrast, the curve-fit performance did not degrade significantly at the lower integration time. At 200 and 2000 nA s, precisions were best at 63 ms integration time, while the lower signal levels gave slightly better results at 250 ms integration time.

Precisions for the higher SS are superior to those for the lower SS at all levels. At the lowest signal level investigated, the $SS=0.8$ summation method failed to detect peaks reliably while the $SS=0.1$ method produced highly inaccurate and imprecise ratios. The summation results are also seen to deviate substantially from the reference

Fig. 2. $\delta 45$ deviations from reference values for 63 ms integration rate using the three different integration methods: \blacksquare = SS 0.8 mV/s; \bullet = SS 0.1 mV/s; ∇ = curve fit. Points for SS = 0.8 mV/s and fitted data are offset their actual signal level for illustrative purposes. Data of a is plotted in b with expanded ordinate.

levels. This observation is consistent with our previous report, and may also explain inaccuracy observed for highly enriched material at low sample levels [18]. In fact, S.D.s improve with shorter integration time for the strongest signal level.

Summary data of $\delta 45$ values are presented in Table 1, tabulated using average signal levels (in nA s), along with reference values from the equimolar mixture. Precisions (S.D.) for the reference values were all $\delta^{13}\text{C} < 0.4$ which are consistent with our routine measurements under nearly ideal GC-C-IR-MS conditions. The SS = 0.8 method detected only one peak at the lowest level across all integration times. Precisions and accuracy for the curve-fit data are superior for all but one cell.

Accuracy was assessed by statistically testing mean deviations for equivalence with zero. All of the 20 nA s deviations for the SS = 0.8 method were significantly different from zero, indicating systematic shifts in measured isotope ratio

Fig. 3. $\delta 45$ deviations from reference values for 125 ms integration rate. Symbols as in Fig. 2.

Fig. 4. $\delta 45$ deviations from reference values for 250 ms integration rate. Symbols as in Fig. 2.

^b Mean and error for SS = 0.1 mV/s (2000 nA s) excluding one aberrant determination.

for signal levels below 200 nA s using this method. The SS = 0.1 method showed significant differences for only the 63 ms integration time, but gave very large errors for all but the 250 ms integration time. At the 3 nA s level, where the higher SS failed to detect peaks, the SS = 0.1 method produced large errors ($\delta^{13}\text{C} > 300$) and statistically different mean isotope ratios. In contrast, only one of twelve fitted means is different from the reference values (63 ms, 200 nA s) at 95% confidence.

The relatively high quality of the curve-fitted data at low levels prompted investigation of the preservation of peak area with decreasing sample size, for quantitative analysis. Graded solutions of pure Me17:0 in hexane were injected at levels from about 10 pmol to 500 nmol C. Areas for the m/z 44 signal were obtained by each of the calibration methods and summary data are plotted in Fig. 5, in log-log format. Peak areas below about 1 nmol are not accessible in our version of the vendor software and so are not presented. The SS = 0.8 method parallels the curve-fit method to 1 nmol, while the SS = 0.1 method diverges, with slopes and S.D.s for the

two methods of $6 \cdot 10^{-3} \pm 6 \cdot 10^{-6}$ ($r^2 > 0.999$) and $5 \cdot 10^{-3} \pm 20 \cdot 10^{-6}$ ($r^2 < 0.99$), respectively. The curve-fit method provides good linearity down to 10 pmol, with slope and S.D. of $5 \cdot 10^{-3} \pm 6 \cdot 10^{-6}$ ($r^2 > 0.999$) over this range.

The Finnigan MAT 252 instrument is specified to operate at an absolute sensitivity of 1000 CO_2 molecules/ion detected, and typically attains this

level. For such an instrument, the 2000 nA s area would be produced with about 5 nmol C entering the combustion furnace, while the 3 nA s level would be attained with 5 pmol C. It should be emphasized that these detection limits are based on molar C content, and so are largely independent of the analyte molecular mass for most organic molecules of biomedical interest. These data indicate that curve fitting produces useful isotope ratios at this level of total analyte.

4. Conclusions

For tracer applications, a cutoff for "high precision" can be defined as an error of $\delta^{13}\text{C} = 100$ (S.D.), which corresponds to 0.1% in absolute terms and to the practical limit of organic mass spectrometers operated in selected ion mode (SIM) [2]. The $\text{SS} = 0.1$ mV/s detected peaks at levels below the $\text{SS} = 0.8$ mV/s method, but produced S.D.s greater than $\delta^{13}\text{C} = 100\text{‰}$ in most cases at the lower levels. $\text{SS} = 0.1$ did perform better for the largest integration time and lowest signal, further suggesting that the summation methods require a minimum S/N for adequate performance. For this reason, it appears that the higher value for SS is appropriate when using the summation method, as it detects peaks down to levels at which high precision is obtained. In cases where very small peaks must be detected by summation, consecutive data points can be summed to improve S/N per data point, with a lower SS then applied to the resulting chromatogram.

At all levels, curve-fitting produced satisfactory precision and accuracy, and was nearly immune to the choice of integration time. It was the only method that produced useful isotope ratios at the lowest levels. It also gives linear response over the entire usable dynamic range and so is also suitable for quantitative analysis. Our previous results showed that curve fitting satisfactorily recovers aberrant isotope ratios derived from overlapping peaks [12]. Together, these studies indicate that curve fitting may be the method of choice for integrating peaks in

high-precision chromatography applications where complex mixtures are commonly encountered.
